Taxation of Research.

THE question of the taxation of educational and scientific institutions has very recently come prominently before the public, and indications exist that the Treasury is contemplating an important change in connexion with the policy hitherto pursued in granting exemption from income-tax to such institutions. The recent judgment of the House of Lords in the case of the Brighton College *v.* Marriott amounts to a declaration that any profits of an educational establishment which are used for educational purposes are the result of carrying on a trade and therefore taxable. The judgment in question may have far-reaching consequences, for it must be remembered that Brighton College is not only a public school, but also a "charitable institution." Following closely on the above-mentioned judgment comes the public announcement from responsible officers of the Chemical Society of the receipt by this Society of a notification that the Inland Revenue authorities are about to challenge its right, as a "charitable institution," to recover the tax deducted at the source from the interest on its invested capital (see NATURE, June 19, p. 859).

The matter was carried a stage further on June 21, when the question of exempting certain classes of educational institutions from income-tax in respect of any profits forming part of their income which was applicable to educational purposes *only*, was raised in the House of Commons in connexion with the suggested new clauses to the Finance Bill (see "Parliamentary Debates," vol. 197, No. 86). The Chancellor of the Exchequer, in dealing with the matter during the debate, indicated that he was unwilling at the present time to extend the limits of exemption of 'charities,' and admitted that, in view of the judgment in the Brighton College case, it was likely that some institutions which in the course of previous years had not been called upon to pay, might, during the course of the year, on the merits of the particular case, be brought into the ambit of taxation for the first time.

Although unable to hold out any expectations that he would make any proposal before the report stage of the Bill, Mr. Churchill stated that he could not feel that the present restrictions, though necessary, were the last word that should be said in defining what was a 'charity' deserving of exemption from income-tax and what was not; he undertook, therefore, to examine very carefully whether the frontiers of charitable exemptions could not be defined with some nearer approximation than at present.

The question of the exemption of 'charities' from income-tax is briefly reviewed in the Report of the Royal Commission on the Income Tax (1920, Cmd. 615, p. 67; H.M.S.O., 3*s*. net); *inter alia*, the Commissioners say: "The issues involved in this matter are very wide; we have taken no evidence on the general question and we think it is not covered by our Terms of Reference. We therefore content ourselves with expressing the opinion that for the purposes of Income Tax 'charities' should be specifically defined by Parliament." It is to this recommendation, then, that Mr. Churchill has undertaken, if it is possible effectively to do so, to give effect. It is perhaps significant that the Commissioners point out that "attempts made in the past, notably by Mr. Gladstone in 1863, to repeal or curtail the relief enjoyed by charities aroused strong opposition and that in the end nothing was done"; they further state that "any proposal for limiting the exemption would have a serious effect upon the available income of many institutions." It is hoped that Mr. Churchill will give due weight to the foregoing observations.

The legislature has not entirely overlooked in its taxing statutes the claims of scientific institutions, as such; indeed, in the first of the Income Tax Acts, that of 1842 (5 & 6 Vict. c. 35), provision was made for exempting from income-tax certain premises of institutions existing for the promotion of education, literature, science and the fine arts. Again, in an Act of 1843 (6 & 7 Vict. c. 36), provisions were inserted entitling such institutions, under extremely strict conditions, to exemption in respect of local rates. Later, when corporation duty was, as a compensatory measure, first imposed under the Customs and Inland Revenue Act 1885 (48 & 49 Vict. c. 5) upon the yearly value, income or profits accruing from real and personal estate permanently vested in bodies, corporate and unincorporate, which escapes liability to probate, legacy and succession duty, provision was again made for exempting such institutions from the duty in question. At the present day a scientific institution, as such, is entitled to exemption from income-tax under Schedule A (property tax) in respect of any building which is the property of such institution and is used solely for its own purposes. No payment may, however, be demanded or made for any instruction therein by lectures or otherwise, nor may the building be occupied by any officer or other person paying rent for the same (Income Tax Act, 1918, 8 & 9 Geo. V. c. 40).

A latent intention on the part of the legislature to benefit scientific institutions to some extent, great or small, is certainly present in the statutes referred to above, and at various times scientific institutions have endeavoured to avail themselves of the privileges in respect of exemption from taxation which seem to be offered to them. But how extremely difficult it is for such institutions to satisfy the Courts that their constitution and activities are of the character to qualify them to obtain the benefits which, to an ordinary layman, it seems that the legislature intended such institutions to enjoy, can be gathered from an examination of the cases in the Law Reports which relate to the claims for exemption from taxation made under the provisions of statutes particularly applying to them. It will be found that even on a particular set of facts, eminent judges have sometimes held opposing views in regard to the right to exemption.

Briefly stated, to obtain exemption from income-tax or corporation duty under the provisions of the abovementioned statutes, a scientific institution has to satisfy the Courts that the primary object of such institution is the promotion of science in the abstract; its property and income are legally appropriated by a Royal Charter or other compelling instrument and applied in fact to that object; and further, if the object of the professional interest of its members is to be inferred, this must at least be secondary to the main and chief object. In consequence of the foregoing state of affairs, the important partial exemptions from income-tax which accrue to scientific institutions, as a rule, are granted, not by reason of the provisions of the statutes conferring privileges specifically on such institutions, but under the provisions of taxing statutes containing an exemption in favour of property dedicated to 'charitable purposes,' an expression which in a legal sense has an extremely wide meaning and is applied to all trusts known to the law of England as 'charitable uses.'

The great value of the work done by the members of the leading scientific institutions has not been contested at any time. It is fully recognised that such institutions are great clearing-houses of specialised knowledge and that they greatly stimulate scientific research. In thus promoting the advance of science and the development of industries, scientific institutions confer considerable benefits, indirectly it is true, on the whole community, and it is desirable therefore that nothing shall be done which may restrict their usefulness. A strong case can really be made for giving the widest interpretation to the exempting clauses of statutes under which scientific bodies are at present entitled to enjoy remission from taxation; further, it is certain that the national exchequer would gain more from measures taken to secure this end than from the adoption of a course which may result in seriously cutting down existing privileges.

Rust-Resisting Steels.

Stainless Iron and Steel. By J. H. G. Monypenny. Pp. ix + 304 + 22 plates. (London: Chapman and Hall, Ltd., 1926.) 21*s.* net.

THE loss to our civilisation through the rapid attack by atmospheric and marine influences upon the iron and steel upon which it is really based has been estimated by Sir Robert Hadfield to reach the large sum of 500,000,000*l.* per annum. There is no need to criticise such an estimate, since obviously the computation is necessarily only achieved by empirical methods. The fact, however, is that there has been probably no more useful field for pure and applied science than that provided by the problem of producing rust-resisting steels.

It may be said that two decades ago the metallurgical world did not seriously contemplate the production of rustless steel as likely to be an early practical achievement; not because investigators were not giving much attention to the subject, but rather because of the curious misapprehension concerning the nature of the laboratory tests that were likely to give indication of resistance to atmospheric attack. This, of course, means that there was no accurate appreciation of the true mechanism of corrosion. For example, the literature teems with experiments upon the degree of resistance of iron and steels of diverse composition to sulphuric and hydrochloric acids of different concentrations. These acids attack the metal with the liberation of hydrogen. Such acids are not usually prevalent under natural conditions, and the rustless steels now produced which resist ordinary corrosion are not passive to the acids mentioned.

Mr. Monypenny is to be congratulated upon having produced a book of merit, in which will be found a reasonably full and accurate account of the composition and characteristics of the rustless steels which are now available. The development of these steels has been particularly rapid, and is based, fundamentally, upon the alloying of the metal chromium with the steel. If experimental samples are prepared from a range of steels of low carbon content, but with gradually increasing chromium content, and are placed in nitric acid of spec. grav. 1·20, it will be found that when a chromium content of 10 per cent. is passed, almost complete passivity is attained. The phenomenon can be, at present, satisfactorily explained by the assumption that a protective film of the desired characteristics is immediately formed on the surface of the specimen, which inhibits further action. Such explanation is completely in accord with experimental facts to date. Laboratory tests with nitric acid appear to be indicative of resistance to ordinary atmospheric effects. If, however, the range of corroding media is extended, such a simple form of test fails, and hence the practical extension of the employment of such steels to a wider range of corroding media has necessitated practical experiment under the necessarily complex actual service conditions, coupled with the gradual modification in the composition of the steel to meet those conditions. The development has taken the direction of increasingly high chromium content together with the addition of nickel. It is also claimed that other elements can be advantageously added.

If the steelmaker is to use the metal chromium in quantity, he is dependent upon his supplies of the metal, which is usually in the form of the alloy ferro-chromium. Until comparatively recently, the supplies of ferro-chromium available were very high in carbon content, but the rapid development in the metallurgy of chromium reduction has now rendered available rich alloys of chromium and iron of suitably low carbon content. These developments are made possible by the use of suitable electric furnaces and cheap power. When it is also recorded that the rustless steels are best prepared in electric steel-making furnaces, it will be realised that here, as in many other developments, the actual application of the discoveries has been dependent upon parallel progress in entirely dissimilar fields of investigation and technology.

Turning to Mr. Monypenny's book, it will be found that after a short historical account of the development of the steels, the results of a detailed study of the influence of chromium are given. The succeeding sections of the book are devoted to practical notes on the handling of the steels in various manufacturing operations, such as forging, welding, pickling; the effects of heat treatment on the mechanical and physical characteristics; and the "resistance to corrosion" as affected by composition and treatment. So far, the book, generally speaking, deals with the simple carbon chromium steels. The next section deals with the newer types of rustless steel. The principal item in this connexion is the 'austenitic' type of material obtained with the increased chromium content together with a substantial addition of nickel. The final section of the book indicates various applications in which these steels have been found successful and, incidentally, gives practical notes and hints, which should be of considerable value to intending users.

Generally speaking, the matter dealt with is clearly and logically arranged, and the reader should find little difficulty in obtaining the information he desires concerning the main characteristics of the materials, and in following the main arguments. The work is, naturally, not of the reference type where the answer to a particular problem can be readily obtained, but

rather one for the student, who, by relating the various facts represented, can find out for himself the answer to many of his problems. The book will be welcomed as covering a field which is so comparatively new that adequate treatment has not previously been given to it.

There are a few points where the author's handling of the subject is open to criticism. Much of his data for typical stainless steels is obtained on alloys containing 11 to 12 per cent. of chromium, whereas practice has established the best range as being between 12 and 14 per cent. On p. 46, in dealing with heterogeneity, the statement is made that after freezing, diffusion of carbon rapidly takes place. This is only relatively true, and, in any case, only applies to diffusion on a microscopic scale. In a mass of moderate size, diffusion of the carbon is very slow indeed.

The deduction made by the author in Chap. v., that sulphur, when present in stainless steels, "obviously is not present in the same form as in ordinary steels," will require experimental proof. On p. 103 the value of maximum stress in torsion for a sample of 55 tons tensile stainless material is apparently the value deduced on the assumption that the torque at this stage gives a distribution of a stress similar to that when the strain is entirely elastic. The real value of maximum shear stress is probably much less than this.

With regard to the author's treatment of the influence of other elements than the essential chromium and nickel on the characteristics of these steels, we have an impression that the deductions are a little hastily formed on perhaps too little experimental data. This is best instanced in the case of the influence of silicon. The author's comments concerning the influence of this element are not in accord with the fact that a very considerable tonnage of stainless steel is used with a silicon content round about 1·0 per cent., and had the author more thoroughly explored this particular field, both as regards the composition of his samples and the variation in the hardening and tempering temperatures, he would not have been led to the conclusion that silicon so readily induces brittleness.

In discussing the non-production of very high tensile stainless steel-drawn wire, the reason given by the author on p. 138 does not appear adequate. The 'hardening-up' effect should help rather than hinder the production of high tensile properties. The present writer considers the difficulties in the way of such operations are due to other causes.

More data are obviously needed on the austenitic chromium-nickel steels, and in this respect the special adaptability of such materials for many purposes might have been emphasised to a greater extent. The superiority of such materials, from the point of view of corrosion, over the stainless steels, is so pronounced as to constitute an advance in the problem of resisting corrosion only comparable with the initial introduction of the chromium steels.

Mr. Monypenny is to be congratulated upon the production of an excellent work. The book is handsomely produced, and the reproductions of the photographs and microstructures are a credit to both the author and the publishers.

Nature-Gods.

The Worship of Nature. By Sir James George Frazer. Volume 1. Pp. xxvi+672. (London: Macmillan and Co., Ltd., 1926.) 25*s*. net.

THIS volume contains the author's twenty Gifford lectures for 1924 and 1925, expanded and regrouped into sixteen chapters dealing with the worship of the sky, the earth, and the sun. It is to be followed by another which is designed "to complete the survey of the worship of the sun, and to deal with the personification and worship of other aspects of nature, both inanimate and animate," or, as the publishers' announcement has it, "the worship of the Moon, the Stars, Fire, Water, Wind, Plants, and Animals." The "Worship of Nature" is thus the counterpart of the author's last previous compilation, "The Belief in Immortality and the Worship of the Dead"; and in the present "Introduction" (p. 17) he indicates his belief that if "we survey the natural religion of primitive peoples in all parts of the world, we shall probably discover that it everywhere assumes one of two forms which, far from being incompatible with each other, are usually found to be embraced simultaneously and with equal confidence by the worshippers. One of them is the worship of nature, the other is the worship of the dead."

This survey of the "natural religion of primitive peoples in all parts of the world" Sir James Frazer has not achieved yet. In his three volumes on the "Belief in Immortality and the Worship of the Dead," he dealt only with Micronesians, Polynesians and the natives of Australia, the Torres Straits Islands, New Guinea, and Melanesia, and then stopped. In examining the "Worship of Nature" he has selected as arbitrarily; taking in turn, for the worship of the sky, the 'Aryan' and the non-Aryan peoples of antiquity (with the curious omission of Celts and Teutons), the 'civilised' peoples of the Far East (omitting among others the Japanese); then Africa (in four main sections), and nothing more. For the worship of the earth the specimen peoples are similar but not identical; Vedic Indians, ancient Greeks, Romans, Babylonians and Assyrians, Egyptians, Chinese, peoples of modern India, Africa, and America; and for the sun (in this volume), the same, with the omission of China, Africa and America,

and the inclusion of the Arabs, Japanese, and Indonesians.

Reasons for selecting these peoples are not given, except that by contrast with the procedure adopted in Pettazoni's "L' Essere celeste nelle credenze dei populi primitivi" (Rome, 1922), the "superior antiquity of the documents" about Aryan beliefs, and the "higher interest" of them, are regarded as justification for treating these beliefs first. Consequently, the separate chapters stand in no organic connexion with each other; there is no attempt made to compare their contents, or to draw any general conclusions. Even on the connexion between the sky-gods of various Aryan peoples there are only the briefest observations (p. 36), and on the significance of Ahura Mazda the compiler is "content to record the two views without attempting either to judge or to reconcile them" (p. 35). From the author of "The Golden Bough" this is disappointing.

Within the separate topics, the method is that adopted in "The Belief in Immortality": to select the most trustworthy authority, and summarise the principal statements in more or less systematic order; but what the system is, we are left to judge for ourselves. But whereas in Micronesia, for example, this method is so far justified that there is usually only one authoritative record for each people, or at most the observations of two or three observers, its application to peoples who have been so carefully and repeatedly studied as the Aryan peoples of antiquity has an appearance of economy of effort. The chapter on the worship of earth in China, for example, is almost wholly extracted from Chavannes' "Les T'ai Chan" (Paris, 1910); in Babylonia, from King's "History of Sumer and Akkad"; in Egypt, from Wiedemann and Erman; and on the worship of the sun in Japan, from Aston's "Shinto, the Way of the Gods." The result is very readable, diverting in its frequent long episodes quoted verbatim, its eloquent verbal landscape-painting, and its sardonic and sometimes broad humour at the expense of the more ingenuous "devices of the heathen"; but it does not advance learning greatly. In the work of a beginner it would run the risk of being described as the method of "scissors and paste"; in that of a veteran, we naturally look for another explanation. But Sir James Frazer does not help us. Is he insinuating that there is nothing more to say, except that this and that people may be accepted as worshippers of the sky, earth, sun, and the like; or is he speaking to us in parables, and reserving his own conclusions for yet another volume? The lame conclusion of "The Belief in Immortality" (p. 326) favours the former inference: "accordingly, we are justified in concluding that the belief in immortality and the worship of the dead were fundamental features of the ancient Micronesian religion," as if it were possible in any intelligible sense to speak of "the" ancient Micronesian religion, any more than of "the" ancient Micronesian race.

Occasionally, however, something rather more positive is foreshadowed. Summing up an account of the Shilluk and Lango chief-gods, whose name *jok* or *juok* means in the Dinka language "the spirit of a dead ancestor," Sir James Frazer is at some pains to contest the obvious inference, on the strength of "the analogy of African sky-gods or Supreme Beings in general," who, for the most part, he thinks, "are sharply distinguished from the ancestral spirits not only in name but in function"; and so, in spite of the embarrassing *jok*, he concludes that "so far as they go, these facts support the view that African sky-gods or Supreme Beings in general are not deified ancestors, but simply personifications of the great celestial phenomena, whether the sky, or the rain, or the sun"; a thesis which we should like to hear him defend before a jury of *jok*-ists.

From this and a few similar hints, it looks as if Sir James Frazer's contribution to the "natural theology" which the Gifford lectures were founded to elucidate may turn out to be a "spiritualistic hypothesis," as he calls it in his introduction (p. 10), which "has undergone a process of simplification and unification analogous to that undergone by the materialistic theory: as the materialistic hypothesis has reduced the multitudinous forms of matter to one substance, hydrogen, so the spiritualistic hypothesis has reduced the multitude of spirits to one God." But it is not quite clear how far the copious information collected in this volume is intended to take us in the verification of this hypothesis. Sky-gods, and earth-gods, and sun-gods, are about as much like the "one God" of the spiritualistic hypothesis as hydrogen is to the "one substance" of the materialist. All that emerges from this first volume of Sir James Frazer's new book is the rather cautious generalisation that some people worship some nature-gods. But perhaps the second volume may go further.

The Periodicity of Earthquakes.

Die Frage der Periodizität der Erdbeben: eine Darstellung des gegenwärtigen Standes der einschlägigen Untersuchungen. Von Prof. Dr. Ernest Tams. (Sammlung geophysikalischer Schriften, No. 5.) Pp. ix + 128. (Berlin: Gebrüder Borntraeger, 1926.) 9·60 gold marks.

OF those who have studied earthquakes, few have escaped the lure of earthquake statistics, or failed to attempt the detection of some influence, external to the earth, in determining, or at least

influencing, the time of occurrence. For some it has been an introduction to seismology, to some also the end of their activity in this field, to others merely an incident in a wider treatment of the subject, but sooner or later the call comes to all, and is always fraught with danger. Figures have a fascination which may be fatal; once involved in them the temptation is great to try them in one way after another until some definite conclusion seems to have been reached. The literature of the science contains many examples of such misdirected labour, often simply useless, sometimes misleading, much of which would have been avoided had those who knew their earthquakes been also acquainted with the principles of statistical investigation, or those who were familiar with mathematics understood the character of the data with which they dealt.

To the latter class the book under review makes small appeal; to the former it will be useful. Of the two parts into which it is divided, the first is devoted to a description of the methods which are used in computation; the regular method of harmonic analysis is described in sufficient detail, as also is the approximate method of overlapping means, elaborated by Dr. Davison, and in both cases examples of working are given. The author decides in favour of the latter, for ordinary use, as giving similar results to the former, with sufficient accuracy and with a much less laborious computation; but he does not seem to be acquainted with a simpler method of analysis than that described, which takes no longer, and uses no more paper, than the Davison method, besides having the advantage of giving a result in the form conventionally adopted, and with greater precision, though with not greater real accuracy. This last mentioned has, however, on its part, an advantage, in that the computation proves itself at every stage, and mistakes can be detected immediately, whereas in the other method the only proof possible is a repetition of the entire calculation, from beginning to end. Finally, a section of this part of the book is devoted to the consideration of variations in frequency due to causes which are not periodic in their recurrence.

As a whole, the treatment is satisfactory and adequate, but there are two points which do not seem to be sufficiently emphasised. The first, and it is one which it is important to impress on those to whom the work is addressed, is that while a given periodicity may be expressed as the sum of a series of harmonic periods, harmonic analysis does not assert that it must be interpreted as the result of such combination; in other words, the method can only be properly applied where the cause of the effect looked for is one that acts in a manner which makes the method applicable. The other point not dealt with, though even more important, is that where the record is so imperfect, and the data so unprecise, as in any non-instrumental record of earthquakes, it is essential to deal with averages of a large number of shocks. A somewhat extensive experience has shown the reviewer that the lower limit of this number must be put at about 400 times the number of separate groups into which the series has to be divided for the purpose of discussion. If the effect to be investigated needs a division into only two groups, then a record covering 800 shocks may suffice, but for anything analogous to a harmonic analysis, at least four times this number are required; needless to say, the more the number exceeds these limits the better, so long as the record is homogeneous for the purpose in view, but smaller numbers will give irregular and contradictory results.

The second part of the book is devoted to a consideration of the different periods, correlated with the solar or lunar day, month, year, or longer periods, and the non-periodic variations which have been correlated with variations in barometric pressure, rainfall, shifting of the poles, and so on. The treatment is rational and sufficient, and the conclusion come to by the author may be fully accepted, that though, in several cases, it has been shown that the cause investigated may possibly have some small effect in determining the time of occurrence of an earthquake, the connexion has not been established in any single instance.

The conclusion might have been strengthened had some recently published papers reached the author, by which doubt is cast on the reality of some periods which might naturally be expected to exist. Prof. H. H. Turner has suggested that the so-called annual period is not really annual, but differs from the exact year by about ten hours, so that the epoch of maximum frequency works round the calendar in about 850 years; and the Italian record, by far the most accurate and complete of any that is available, indicates that the maximum frequency, of the well-marked diurnal period, has advanced steadily through the thirty years which have been tabulated, at the rate of about five minutes a year. If these small differences are real, what is the meaning of the periods of about ten hours less than twelve complete months, or about three-quarters of a second more than twenty-four hours, respectively? They cannot be correlated directly with the revolution of the earth on its own axis, or round the sun, and they throw doubt on the exactitude of other periods which are supposed to have been detected. Everything is in doubt; we have no proof, or even reasonable probability, of the existence of any periodicity, and those who think that they have time to spare for the pursuit may find justification for an attempt to succeed where others have failed.

Among the variations in frequency which might be attributed to influences external to the earth, the one which shows the nearest approach to probability is the slightly greater frequency of shocks during the day, and the correspondingly lesser frequency at night, in summer as compared with winter. As this has been found to hold good for every suitable record which has been tested, and as it also holds good, with the necessary change in nomenclature, for lunar times and seasons, it may be accepted as a fairly well established fact. Seeing that it is also just such a variation as might be expected, if the gravitational stresses, set up by the sun and moon, had some effect in determining the time of occurrence of an earthquake, the two may reasonably be correlated as cause and effect. But if—and the reservation is an important one—this conclusion is correct, then the smallness of the effect shows how trivial is the influence of the cause, and how predominatingly the earthquake is a phenomenon of the earth, earthly.

Sir Walter Raleigh.

The Letters of Sir Walter Raleigh (1879–1922). Edited by Lady Raleigh. Vol. 1. Pp. xxix + 272 + 4 plates. Vol. 2. Pp. xv + 273-579 + 5 plates. (London: Methuen and Co., Ltd., 1926.) 30*s*. net.

IN this selection from his private letters we have a portrait drawn by his own hand of the late Sir Walter Raleigh, well known in academic circles as a distinguished critic and man of letters, and among his intimate friends as one of the most engaging and delightful companions. To have read Raleigh's books was not enough. He had a side not to be found there, in some ways still more interesting and attractive. Admirable as his writings were, many of his acquaintances prized them less highly than his conversations, when he was wholly himself, less weighted with a sense of responsibility, and accustomed to give a free and joyous vein to his whimsical humour. For Raleigh's social gifts were such that, though he preferred light to serious subjects, his hearers were too content with the fare he provided to ask for any other. So delicate was its flavour that his brand of nonsense was, for so long as he cared to distribute it, better than any sense. Nor was this surprising, for it was a nonsense sparkling with intelligence, and far removed from that 'silliness' which he disliked in man and books. It was his way to approach truth by way of humour, and to judge even of his own writings by the standard of good sense, the standard of things able to survive all humorous assaults upon them, as when he said of his "Shakespeare," "I don't want to write anything that William himself would have thought rot."

These volumes are, in Raleigh's case, a supplement, and an important supplement, to his public utterances. If they are less carefully considered, they are, because more spontaneous and instructive, a better index to his mind and character. His letters cannot replace, indeed, the charm of his conversation, but they recall it, and preserve some quality or relish of it for those who had never the fortune to hear his living voice. He enjoyed talking on paper to his friends, as he enjoyed talking to them in person, and in these letters he is speaking rather than writing. There are wines that will not bear bottling or exportation, and often the qualities in a man adjudged the most attractive by his contemporaries are either wholly hidden from succeeding generations, or but dimly guessed at. Certainly the future, which can only judge of Raleigh by his books, will miss something of the singular pleasantness that informed his daily speech. The letters cover a wide range of topics, from his early experiences as a professor in Aligarh to the late War; too wide to be illustrated by quotation, but certainly not the least interesting, are those written soon after he left Cambridge, "the place of my early friendships, dreams and idleness," which reflect the impressions of the scenery and society of the East upon a mind quick to receive and eager to record them.

Raleigh's interests, it may with truth be said, were human rather than bookish; for a professor and writer, indeed, unusually remote from the study. He would rather, he said, "have missed Cambridge than India"; and was never quite convinced of the value either of lectures or examinations. Academic machinery creaked rather dismally in his ears. The play of life as it passed before his observant eye had a fascination for him beyond anything that the poets or historians had to say of it, a fascination that into words no virtue could digest Life, he felt, needed no assistance from the artist to give it either interest or significance.

Raleigh emphatically placed living above art or science, and had more sympathy with men and their doings than with the makers of books about either. For this reason his most passionate admiration went out to adventurers, and more especially to young adventurers, the high-spirited soldiers, or voyagers or airmen, rather than to those who recorded or sang of their exploits. That his life should have in the end been sacrificed to his enthusiasm for, and determination to do justice to, the pioneers of flying is a sufficiently convincing proof of his preferences, and it was characteristic of him that as an Oxford professor, past middle life, he drilled and marched and did what he could to make himself a soldier. "The last three days I've been marching and lying out on the Downs in torrents of rain, and housed in billets. Billets is 60

beds for every 100 soldiers. . . . Weather disregarded. You have to get through barbed wire like a knife, and tear your clothes much or little."

Sir Walter's friends owe a debt of gratitude to Lady Raleigh for these volumes, and to Mr. Nichol Smith for his brief but admirable memoir of their author, for they will recall many delightful hours in his company. In all their readers they cannot but arouse regret that so rare a spirit has passed beyond the term of human acquaintanceship.

Our Bookshelf.

The Petrology of the Igneous Rocks. By Dr. F. H. Hatch. Eighth edition, revised with the assistance of Dr. A. K. Wells. Pp. xxiv + 566. (London: George Allen and Unwin, Ltd.; New York: The Macmillan Co., 1926.) 15s. net.

WITH the collaboration of Dr. A. K. Wells, this well-known text-book has been revised and extended until now it is virtually a new book. Among the new features are chapters dealing with the consolidation of magmas; the classification of igneous rocks; changes in composition subsequent to consolidation (including pneumatolytic, hydrothermal and other phases of metamorphism as well as weathering); petrographic provinces; and cycles of igneous activity in the British Isles.

Dr. Hatch was a member of the Committee on British Petrographic Nomenclature (1920), and he has naturally adhered to most of the decisions then reached. A welcome simplification of the unwieldy nomenclature of the subject has been achieved, but unnecessary confusion has been introduced by adopting first a classification of types into *acid*, *intermediate* and *basic* divisions, and then a subdivision of some of the groups, such as the syenite group, into *oversaturated*, *saturated* and *undersaturated* divisions. The term 'acid' is sometimes used to mean that a rock is oversaturated, and sometimes to imply a silica percentage not less than 66. It is a pity that the older terms were not altogether dropped. On p. 186 the terms *salic* and *femic* are wrongly used for *felsic* and *mafic* respectively. A useful suggestion due to Prof. Watts has been adopted: the naming of a rock according to its texture with the qualifiers 'intrusive' or 'extrusive' added where necessary. Thus one may have an *intrusive basalt* or an *extrusive dolerite*, and a common source of futile indecision among students is thereby removed, in the only logical way.

The book is now thoroughly up-to-date. It contains abundant references to the splendid work carried out at the Geophysical Laboratory at Washington. Heteromorphous rocks are discussed, eclogite being recognised as a heteromorphous phase of gabbro. The work of Dr. Brammall and Dr. Harwood on the minerals of the Dartmoor granite is included, and the book may be said to present a very complete and well-balanced survey of the subject up to the end of 1925. Controversial and speculative matters are wisely given little space, and students using the book may rely upon it as a sound and authoritative exposition of a delightful subject.

Applied Chemistry: a Practical Handbook for Students of Household Science and Public Health. By Prof. C. Kenneth Tinkler and Helen Masters. Vol. 2: *Foods.* Pp. xi + 276 + 3 plates. (London: Crosby Lockwood and Son, 1925.) 15s. net.

THIS book deals with certain branches of the chemistry of foods which have particular interest to students working for the B.Sc. (Household and Social Science) degree of the University of London. It forms a companion volume to that produced by the same authors in 1920 on water, detergents, textiles, fuels, etc. The general treatment is elementary, but the authors have adopted the policy of giving references to standard works wherever possible. In addition to such subjects as milk, edible oils, foods their analysis and calorific value, raising agents, vinegar and preservatives (subjects which are found generally in food analysis books), a separate chapter on the cooking of foods is included. In introducing this somewhat novel subject in an elementary text-book, it is explained that this operation is still primarily an art and not a science, and that our knowledge of the chemistry and physical changes which take place in the preparation and cooking of foods is at present very meagre. Nevertheless, the authors in some thirty-five pages have collected a large amount of scientific data on cooking foods and on the use of condiments, and have given an exceptionally good exposition of the subject.

In many cases interesting chemical determinations bearing directly on food analysis, etc., have been considerably restricted for want of space, yet the determination of specific gravity, specific rotatory (spelt rotatary) power, calorific value, and hydrogen ion concentration—subjects usually well treated in practical physico-chemical text-books—receive a comparatively large amount of attention. The book is well produced with clear diagrams, and the price reasonable judging by present-day standards.

J. REILLY.

Éléments d'astrophysique: introduction à l'étude de l'énergétique solaire et stellaire. Par Dr. Albert Nodon. Pp. viii + 244. (Paris: Albert Blanchard, 1926.) 20 francs.

THE author has produced a useful book of reference based on his public lectures delivered at Bordeaux. The contents are divided into two parts. Part 1 contains some seventy paragraphs, in which are outlined the recent advances in astrophysics made possible by well-known theoretical and practical investigators. Part 2 includes tables of notation, physical constants, explanatory notes, and bibliography arranged with reference numbers so as to amplify the paragraphs of Part 1. Although the book is intended, presumably, for general scientific reading, the arrangement of the subjects will scarcely commend itself to the beginner. Commencing with an account of modern ideas on the structure of the atom and the phenomena of radiation, the author then passes to such matters as the opacity of stellar atmospheres and radiation pressure. Paragraphs dealing with the sun follow those on stellar spectra, giant and dwarf stars, etc.

Many of the illustrations receive no explanation in the text, and a knowledge of instrumental equipment assumed. We consider that the lack of detail in

some of the résumés detracts considerably from their value. No explanation is given, for example, of St. John's schematic section of a sunspot, reproduced on p. 100, neither is any reference to be found to the work of Evershed, A. Fowler, and Maunder on sunspots and their spectra. The usefulness of Part 2 would have been increased by fuller explanation or wider bibliography on matters (such as the distances and numbers of the spiral nebulæ) where conclusions are not yet generally accepted.

The Making of the Future. The Coal Crisis and the Future: a Study of Social Disorders and their Treatment. By P. Abercrombie, V. Branford, C. Desch, P. Geddes, C. W. Saleeby, and E. Kilburn Scott. Pp. xi + 111 + xlvi. (London: Leplay House Press; Williams and Norgate, Ltd., 1926.) 8*s.* 6*d.*; paper, 6*s.*

In this volume the coal problem is attacked from various angles by the several contributors, though a certain coherency is obtained, since most of the writers would appear to subscribe to the viewpoint of the 'sociologist.' The quality is, however, somewhat uneven, and it is to be feared that many readers will become impatient of the terminology and verboseness of certain of the writers. About one-half of the volume is devoted to an account of the "Conditions of Eutopian Repair and Reconstruction." This, though it may interest some readers, would have been improved by compression, as it is somewhat vague and at times irrelevant. The appendices do not appear to bear very directly on the problems of the coal industry. Several of the papers, however, are more concise and contain some interesting matter. Prof. Desch and Mr. Kilburn Scott contribute readable articles on the technical aspects of coal utilisation; Dr. Saleeby pleads on hygienic grounds for the elimination of the smoke nuisance, while Prof. Abercrombie describes the planning of the Kent coal-field on the basis of regional surveys.

Handbuch der Pflanzenanatomie. Herausgegeben von Prof. K. Linsbauer. Lief. 13 (II., 2B.; Bg. 1-4). 2 Abteilung, 2 Teil: *Pteridophyten und Anthophyten.* Band IX. 2: *Die Vegetationsorgane der Anthophyten. Organe besonderer physiologischer Dignität.* A: *Die Absorptionsorgane der parasitischen Samenpflanzen.* Von Prof. Dr. Adolf Sperlich. Pp. iv + 52. (Berlin: Gebrüder Borntraeger, 1925.) 4·50 gold marks.

THE section of this handbook of plant anatomy at present under notice discusses briefly the ascertained facts as to the haustoria of the parasitic or semi-parasitic flowering plants. Dr. Sperlich divides them into three groups: he gives most space to the haustoria of (1) the Rhinantheæ, Orobanchaceæ, and Balanophoraceæ, and (2) the less parasitic Santalaceæ, Loranthaceæ, and Olacaceæ, with which group he includes the wholly parasitic Rafflesiaceæ. He puts in a special section, but discusses very briefly, the more root-like but still morphologically distinctive organ, the haustorium of Cuscuta. Curiously enough, with reference to recent papers recently referred to in NATURE of February 6, p. 210, and subsequent correspondence (NATURE, March 27, p. 452), no citation is given of the paper by Mrs. Thoday (Sykes) upon Cuscuta, and the question of the possible presence and function of the phloem in the haustorium is not touched upon.

Les fleurs de la Côte d'Azur (De Toulon à Menton). Par Léon Marret. (Encyclopédie pratique du naturaliste, 21.) Pp. 428 + 112 planches. (Paris: Paul Lechevalier, 1926.) 40 francs.

THIS flora, which is well illustrated with text figures and some coloured plates, will be found of great service to botanists and plant lovers visiting the Riviera. It is divided into four main sections. In the first portion the native wild vegetation is described and figures are given of the more important wild plants of the region. The second portion is devoted to "Les Cultures ornementales"; that is, the introduced plants to be found in the gardens and parks of the Côte d'Azur. In the third part the industrial plants are dealt with; and finally a large section is devoted to "Les Cultures alimentaires." In the first portion the plants are referred to under their ecological formations, those of the sand dunes, maquis, garrigues, rocky situations, marshes and meadows, and mountains, and much interesting and useful information is given. The illustrations are scattered throughout the volume, and the reader may find it a little difficult to identify any particular plant or to find his way easily about the book. It is, however, a very useful volume and worthy of careful study by any one interested in the rich native and exotic vegetation of the Riviera.

Combustion in the Power Plant: a Coal Burner's Manual. By Thomas A. Marsh. Second printing, corrected. Pp. xi + 255. (London, Bombay and Sydney: Constable and Co., Ltd., 1926.) 12*s.* net.

As the title indicates, this book deals with the author's experience in the operation of steam boilers in central power plants, and in the main with American plants. Thus much of the contents has little direct bearing on conditions elsewhere. Twenty-five per cent. of the space is devoted to describing the coals of the United States and their behaviour in boiler furnaces.

The discussion of the relative suitability of the various patterns of stoker to different fuels does contain information of general application, and the author's experience of this and other problems of steam-raising on the large scale will be useful to boiler-house operators. They will also be entertained, for this is no dignified scientific treatise, and the writer never disdains enforcing an argument by means of an anecdote. H. J. H.

Le radium: découverte de la radioactivité et du radium, origine de l'énergie radioactive, le radium dans la nature, ses emplois usuels. Par F. Honoré. Pp. viii + 145. (Paris: Gauthier-Villars et Cie, 1925.) 18 francs.

M. HONORÉ is a member of the staff of *L'Illustration*, and his book is virtually an enlarged edition of a series of articles which he contributed to that journal. It therefore gives an attractive and popular account of the discovery, manufacture, properties and applications of radium and associated substances, which should appeal to educated members of the general public. Strangely enough, the artificial disintegration of elements by means of α-rays does not appear to be mentioned in this book.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Disposal of Scientific Journals.

THE "Universities' Library for Central Europe" was established towards the end of 1920 in order to co-ordinate and consolidate the securing by gifts, exchange and purchase, British books, journals, etc., for students, teachers and libraries in the universities of Central Europe. The last year or two has seen a change in the character of our work owing to the fact that the urgency for the distinctly charitable aspect of it has somewhat relaxed, and our task, while less serious from this point of view, in other directions has been considerably extended.

We have administered the book-funds of various universities and institutions in Austria, Czechoslovakia, Finland, Germany, Hungary, Poland and Rumania, established small select libraries in six different places abroad, on the subject of international problems, for the use of discussion groups of university students, and at the request of the Under-Secretary of State at the Foreign Office, have assisted the Parish Public Library at Malines, Belgium, with works of English literature. We have also arranged for regular and direct exchange of publications between Russian scientific institutions on one hand and similar institutions in Great Britain, India and Egypt on the other. Acting in conjunction with the League of Nations Committee on Intellectual Co-operation, we have undertaken to accept literature from other European countries for distribution anywhere in the United Kingdom, and similarly, the Universities' Library distributes all over Central Europe books and periodicals received from universities and learned societies in Great Britain.

In response to a suggestion made by the Editor of NATURE arising out of recent correspondence in the columns of this journal, the Committee has agreed to provide within the Society, a clearing-house for the reception and distribution of scientific books and periodicals from and between individuals and institutions in Great Britain. It is apparent that there are many persons and libraries which at times have to dispose of files of periodicals and other surplus works owing to the exigencies of space. This material often has no great market value, and yet no lover of his subject cares to destroy or sell it as waste paper. Even the indiscriminate giving of this literature does not always result in its most advantageous placing, and undoubtedly the systematic collection and distribution of such books and periodicals is a matter of national importance.

The organisation for such a work already exists, as will be seen, in the above Society, but such an addition to its activities will naturally entail some increase of expenditure; this may not be much more than the cost of packing and transport, but even so, the existing very limited funds of the Society are earmarked for its Continental work, and it will be readily appreciated that this Society must depend upon donations in order to enable it to carry out this further extension of its activities. It is therefore with confidence that we appeal to all readers of NATURE to contribute a small sum to enable this work to be fully developed. Any gift, however small, will be gratefully acknowledged. Any person or institution having surplus scientific literature which it is desired to place in a suitable library or other institution in the United Kingdom, is invited to communicate with me at this address.

New Facts regarding the Phases of Migratory Locusts.

THE work on *Locusta migratoria* L., which was published in Russia 1912-14, has been regarded by most entomologists as throwing an important new light on the origin of locust swarms. According to the Russian entomologists, two species, *Locusta migratoria* L. and *Locusta danica* L., are to be regarded as forms of the same species, differing in habits, yet intimately related, in that the two forms may emerge from the same egg-mass, occur in the same hopper swarms, and, as was demonstrated by laboratory experiments, can, by suitably altering the conditions, be changed from one form to the other.

Generalising from the observations of these workers and from the examination of a wide range of examples of migratory locusts from various countries, Uvarov (*Bull. Ent. Res.*, vol. 12, pp. 135-163, 1921) formulated the Phase Theory of the Periodicity and Migration of locusts, according to which periodical swarms are dependent for their inception upon the accelerated breeding of other non-migratory and closely related forms, which persist over a wide range in those countries subject to invasion by swarms. These two forms were named by Uvarov 'phases,' in the case of the South Russian species, the solitary locust being the *danica* phase, and the swarming the *migratoria* phase.

Working about the same time in South Africa on *Locustana pardalina* (Walk.), Faure (*Jour. Dept. Agric.*, Union S. Africa, Sept. 1923) has shown that this locust possesses these two phases, and that the solitary phase, which mingles with the swarms of migratory locusts, is also the locust which occurs on the veldt singly and in small loose swarms during the off-season of the migratory phase.

Another important locust of the Old World is *Schistocerca gregaria* Forsk. (= *S. peregrina* Oliv.), which ranges from India to N. Africa, and occurs as a major pest in some years in the Sudan.

As the result of certain recent observations made by the writer, it is claimed that this locust also comes within the terms of the Phase Theory, in that another species of the same genus (*S. flaviventris* Burm.) has now been ascertained to be the solitary phase of *S. gregaria*.

The opportunity for proving the existence of this relationship, which had already been suspected, was met with when, following the abnormally heavy rains in December 1925, *S. flaviventris* gave evidence of great breeding activity on the Red Sea coast north of Port Sudan early in the present year.

During the previous summer, *flaviventris* locusts could be found singly in this district. After the rains these were attracted to the beds of the watercourses which flow intermittently from the hills on the west towards the Red Sea. Here breeding went on undisturbed for some three months, probably three broods at least being produced, until by March adult locusts very strongly approaching the migratory locust in structure and external appearance were found in large numbers.

The threatened destruction of certain grain and cotton crops compelled the adoption of control measures. Following this, the incipient *gregaria* phase was thrown back to the *flaviventris* phase. This result was due apparently to the thinning out of the hopper swarms by the vigorous use of poison bait.

It is not proposed to draw too sweeping conclusions from these facts, since it is realised that much further work is needed before their true significance can be demonstrated. It is claimed, however, that the following additions to our knowledge have been made; namely, the working out of the main facts of the life-history of the *flaviventris* locust in the Sudan, the observation of the habits of the larval stages of both phases in the field and the proof by laboratory breeding tests, confirmed by field observations, of the convertibility of the solitary hopper into the swarming hopper by the overcrowding of individuals in breeding cages. The reverse process has also been tested with success, namely, the transformation of the black-marked swarming hopper into the green solitary hopper by the segregation of single individuals of the former in breeding cages. These experiments were based on the work of Plotnikov in Russia on *L. migratoria*.

In this connexion it was observed that after the treatment of any area with poison and the resultant destruction of a large proportion of the swarming hoppers, the remaining hoppers, which owing to moulting being in progress or for other reasons had missed the bait, invariably tended to assume the colour of the solitary hopper.

It is believed that in the case of this outbreak on the Red Sea coast, a migration of *gregaria* locusts did not take place. Whereas in March these were plentiful and breeding in the beds of watercourses, in May *flaviventris* adults alone could be found. The last brood, on attaining the winged state, dispersed into the surrounding country, there to assume their solitary life until next winter.

As regards the practical significance of these facts, it is perhaps not too much to assume that should they be found applicable to other regions in the Sudan, the basis for working out a practicable method for the control of the *gregaria* phase may be in sight, since by the early thinning out of the solitary phase in its breeding haunts, the production of the swarming phase can be prevented.

Effect of Polarised Radiations on Animal Metabolism.

IN a previous note (NATURE, February 27, 1926) it was shown that *V. choleræ* and *B. typhosis* grow more rapidly in polarised light than in ordinary light of the same intensity. Further work on the same subject has been continued by us, and a paper embodying the results obtained on the growth of *B. coli* and *V. choleræ* has already been communicated to the *Indian Journal of Medical Research*.

The investigation has now been extended to higher animals, namely, rabbits and guinea-pigs, to see if the metabolic activity is accelerated by exposure to polarised radiations, as suggested by us in our previous note to NATURE as one of the possible explanations for the rise of temperature in the afternoon in the normal individual as well as in certain pathological conditions. The amount of carbon dioxide exhaled by the animals has been taken in these experiments as a measure of their metabolic activity.

Two female rabbits of about equal weight, pure white in colour, were put into two air-tight glass chambers of equal size with plane glass sides just big enough to accommodate the animals easily. Through a tightly fitting rubber cork fixed on the lid, two tubes were provided to serve as inlet and outlet for air. The outlet tube went right near the bottom of the chamber, while the inlet tube stopped short near the lid. Before entering the chambers the incoming air was made to pass through potassium hydroxide solution and a tower containing fused calcium chloride and soda-lime in order to free it completely from water vapour and carbon dioxide. The outgoing air from each chamber, after passing through two U-tubes containing pumice stone saturated with sulphuric acid, was bubbled through a strong solution of potassium hydroxide in potash bulbs with tubes of fused calcium chloride fixed at their ends, as ordinarily employed for accurate organic analysis, and then passed through tubes of baryta water to ensure that the whole of the carbon dioxide was being absorbed by the caustic potash.

The current of air through the system was maintained by means of a filter pump attached to a water-tap. The rate of current in the two systems, as indicated by the number of bubbles in the baryta tubes, was controlled and equalised by means of stop-cocks. Further confirmation of the equal amount of air passing through the two chambers was obtained by allowing atmospheric air to pass through each system, after disconnecting the device for intercepting carbon dioxide from the empty chamber, and weighing the increase in the two potash-bulbs due to the absorption of carbon dioxide. The animals were next put in the chambers, which were enclosed in the two partitions of a darkened wooden box, and control experiments were performed to measure the amount of carbon dioxide exhaled by the animals in the dark in half an hour. Before putting the animals in the chambers they were starved for six hours or more.

The chambers were lighted up with polarised and ordinary light of the same intensity by means of two tubes 7 cm. in diameter projecting from a wooden box containing a 100-watt metallum half-watt opal glass bulb. The lamp was rigidly fixed in front of one of the tubes, and the light in the other tube was obtained by reflection from a pile of plates inclined at the Brewsterian angle. The intensities of the polarised and the unpolarised beams were equalised by interposing blocks of glass placed vertically in the path of the beams until the radiant energy falling on a thermopile from the two sources produced equal deflexions in a sensitive galvanometer. The average polarisation as tested by Savart's polariscope (cf. Wood, "Physical Optics," p. 298, 1923 edition) was more than 90 per cent. For the sake of closer comparison results are given in ratios between the amounts of carbon dioxide exhaled by the two animals per kilogram of the body weight in a constant period of half an hour.

TABLE I.

Rabbit A exposed to polarised light.
Rabbit B exposed to unpolarised light.

Animal.	Weight.	Ratio in dark A/B.	Ratio in light A/B.	Ratio A/B in dark after exposure to light.
Rabbit A . Babbit B .	533 gm. 562 ,,	0·965 : 1	1·050 : 1	0·877 : 1

TABLE II.

Animals Interchanged.

Rabbit B exposed to polarised light.
Rabbit A exposed to unpolarised light.

Animal.	Weight.	Ratio in dark B/A.	Ratio in light B/A.	Ratio B/A in dark after exposure to light.
Rabbit B .	569 gm.	1·009 : 1	1·022 : 1	0·867 : 1
Rabbit A .	553 „			

Note.—The weight of both the rabbits increased during the course of the experiments.

TABLE III.

Guinea-pig A exposed to polarised light.
Guinea-pig B exposed to unpolarised light.

Animal.	Weight.	Ratio in dark A/B.	Ratio in light A/B.	Ratio A/B in dark after exposure to light.
Guinea-pig A .	473 gm.	0·881 . 1	0·969 : 1	. .
Guinea-pig B .	517 „			

Note.—The animals were white in colour, but there was a big dark brown patch on the side of guinea-pig B.

From Tables I. and II. it would appear that when the animals were placed in the dark after exposure to light the order of their metabolic activities was reversed, that is, the animal exposed to the polarised light showed diminished activity compared to its fellow exposed to the ordinary light. This would seem to suggest that there is compensatory rest after the increased metabolic activity induced by the polarised radiations.

Further work is in progress.

Energy Levels of the Carbon Monoxide Molecule.

IN a recent letter to NATURE (vol. 117, p. 376, 1926), Dr. R. C. Johnson shows that the third positive carbon bands are related to those recently discovered by Cameron (*Phil. Mag.* (7) 1, p. 405, 1926), and that the final states of the Cameron bands are identical with the final states of the fourth positive carbon bands As the fourth positive bands are known to belong to the neutral carbon monoxide molecule from Leifson's absorption experiments (*Astro. Jour.*, 63, 73, 1926), Johnson concludes that Cameron's bands and the third positive bands also belong to the neutral carbon monoxide molecule. We have recently completed some experiments on the excitation of the carbon monoxide spectra by electron impacts which support the views of Johnson, and they enable us to extend the scheme of energy levels so that it includes all of the bands of carbon monoxide.

We employed hot cathode discharge tubes and measured the excitation potentials of the several systems by a photographic method. A part of the third positive bands appear at 10·2 volts in agreement with the energy level assigned to them by Johnson, but another set appears at 11·1 volts or at a 0·9 volt higher level. These bands were shown to have the same final states as the set which appears first, and when so analysed, indicate that they originate in a single state 8258 cm.$^{-1}$ above the first set. This difference in levels corresponds to 1·02 volts, in agreement with the difference in their measured excitation potentials. As this difference is rather large to be ascribed to a vibrational shift, we have concluded that the second set constitutes a different system, having final states identical with those of the third positive system but originating in an electronic level 1·02 volts higher than the zero vibrational level of the third positive bands. We shall refer to these bands as the 3A system. Their structure is quite different from the others, whereas they would be expected to be similar if they all belonged to the same system. The following bands constitute the 3A system: λ2295·2, 2389·0, 2489·9, 2597·1, 2711·35A.

Having now separated one set of bands from the third positive system, it is possible to arrange the remaining bands into two series having the same final states and having initial states differing by 2210 cm.$^{-1}$, which difference can be ascribed to a vibrational shift. Thus there are two initial vibrational levels for the third positive system and only one for the 3A system. When the molecule is in such highly excited states it cannot suffer very large nuclear displacements. The same thing is illustrated by the few initial states of the Ångström system.

The third positive bands have usually been ascribed to carbon dioxide, instead of to carbon monoxide, because it was believed that they are of too complex structure to belong to a simple diatomic molecule. However, their relation to the Cameron bands points strongly to carbon monoxide as their origin, as suggested by Johnson. Further evidence that carbon monoxide, and not carbon dioxide, is the origin of these bands has been obtained by the writers in collaboration with Prof. E. F. Barker of this laboratory. Carefully prepared and purified carbon dioxide was excited by electron impacts in a three electrode discharge tube through which the gas was caused to flow at a constant rate (Barker and Duffendack, *Phys. Rev.*, 26, 339, 1925). The gas passed through the region of excitation before it could come into contact with the filament, and oxide coated platinum filaments were used in order to reduce the amount of thermal dissociation, and so the amount of dissociation products that could find their way into the region of excitation was negligible.

With this apparatus, the bands of the third positive system were not observed unless a considerable voltage was applied to the electrodes. When they did appear (and they were always of feeble intensity) they were invariably accompanied by the Ångström bands. Their presence under these conditions can be accounted for by the dissociation that occurs in the discharge at high voltages. When, however, the flow of gas was stopped and the stagnant gas excited in the tube, these bands and the Ångström bands appeared strongly in the discharge at much lower voltages. At the same time the pressure in the tube increased, indicating that the carbon dioxide was being dissociated by thermal action at the filament. It is concluded from these experiments that the third positive bands, like the Ångström bands, belong to the neutral molecule of carbon monoxide.

In possessing the two parallel sets of electronic energy levels, carbon monoxide is, so far as the writers are aware, unique. It probably means that the molecule has two distinct types of spectral terms corresponding to different types of electronic orbits. It may be worth while to consider, as an hypothesis, that one set of levels is made up of triplet terms and the other of singlet terms in analogy with the term scheme for the 'corresponding atom.'

In pursuance of this idea, it would be concluded that the complex structure of the third positive bands may be due to the overlapping of bands from the several levels of the triplet terms. Separations of the order of magnitude as occur in the triplet terms of Mg would result in a superposition of the bands from the several levels and cause an apparent complexity of fine structure. The diminution in the triplet separations in the higher terms would result in a simplification of the structure of the bands originating at these levels, and this may account for the simpler nature of the bands of the 3A system. On the other hand, the singlet levels would produce bands of greater simplicity like those of the Ångström and fourth positive systems.

Hydrogen as Anion.

NOT every one can entertain the wild and woolly west—it is some feat! Still, I should be better pleased, if, instead of entertaining Prof. Lewis, I had led him to be serious and consider the depth of crime he is guilty of in aspersing the character of hydrogen as he has done. Being subversive of all that chemists have taught, the doctrine he preaches, that it is the analogue of fluorine and can act as an *anion* and as bigamist, is not one to be put forward in the light and airy manner he adopts—without considering the consequences. If its effect were confined to the Pacific coast, we here might regard such speculation with complacency—following the example of the Professor's countryman, who, during the civil war, expressed his readiness, rather than that it should come to an end to his disadvantage, to see every drop of blood shed from every vein of every one of his wife's relations. When, however, the morals of Cambridge and Oxford suffer, especially when one whom I long sought to train in the ways of righteousness, whose hand and eye work I have always greatly admired, preaches it as gospel in the tabernacles of Belgian, British and French chemists, I feel bound to protest. Men of his type, with an ever waxing clerical diathesis, are dangerous to society, when they begin to imagine and preach heresy—their accolytes tend to take them seriously, not realising that they are but acting the Huck Finn to some distant Tom Sawyer.

Let us admit that to-day chemistry is mainly a Huck Finn-Tom Sawyer business: any one who was present at the recent Faraday Society discussion on explosions and has listened to talks on tautomerism and polarity at the Chemical Society must see that such is now our condition. We just "let-on": the laboratory is fast passing into insignificance, the close study of *materia chimica* is a practice of the past, the judicial spirit is gone, engulphed in the Scandinavian wave, jesuitry prevails instead.

Prof. Lewis merely "lets on": he has no solid ground of evidence. His contention involves the assumption that calcium hydride is an electrolyte. Hittorf's early definition: "Electrolyte sind Salze" still remains the one concise and consistent statement concerning the facts. No pure binary hydride has yet been shown by valid evidence to be an electrolyte, let alone a salt. Prof. Lewis very properly raps me over the knuckles on account of my reference to potassium—an obvious howler. Incidentally, let me say, nothing is more strange than the way in which blunders are unconsciously made in writing and, being made, remain undetected until after an interval—only recently, when filing my letter, did I suddenly realise what a fool I had made of myself.

Prof. Lewis might, however, have taken the hint I gave him. The Bardwell experiment was not made with the metallic hydride but with a solution of the hydride in an eutectic mixture of lithium and potassium chlorides—both electrolytes. Is it not rational to suppose that only the chloride was electrolysed and that hydrogen was but the product of a secondary change? In other words, that it was displaced by the 'nascent' chlorine—hence its appearance at the anode. Bardwell makes no reference to an evolution or appearance of chlorine but calmly assumes that the hydride acts as the electrolyte. Even Prof. Lewis, I imagine, will not contend that the chlorides are unaffected by the current.

Hydrogen, however, will take care of itself. What concerns me is the future of our science. All my life, an advocate of training in the use of scientific method, I find little or no evidence in our ranks of the complete intellectual probity the practice of the method involves. The young student goes to the university in full honesty of purpose, his parents expecting that he will be trained for his life-work. Instead of science he finds nescience. The consequences are already seen to be disastrous both to scientific and industrial progress. Men who are both rational and reasonable, with some breadth of knowledge and outlook, observant and reflective, fit to take charge of posts of importance and responsibility, are not to be found among young chemists to-day. The wrong type of man is being forced into the profession and, even when one of the right type comes forward, the superficial training that is given but unfits him for the service of the world.

HENRY E. ARMSTRONG.

The Sensitivity of Selenium Cells.

MR. THORNE BAKER's observations on the enhanced light sensitivity of selenium cells actuated by alternating, instead of direct, current (NATURE, June 19, p. 858), are possibly related to some phenomena investigated recently by Mr. J. W. Avery and myself. We have found that selenium cells of a particular type (those made to the design of Prof. H. Thirring) display, when used in the ordinary way with direct current, appreciable and persistent polarisation effects. Almost accidentally it was discovered that this polarisation disappeared as a consequence of prolonged exposure of the cell to the operation of a drying agent. By the same process the 'dark' conductance of the cell was reduced in the proportion of about 4 to 1, while the 'light' conductance was scarcely altered. The dried cell had thus become much more sensitive to light. We have attributed both the polarisation observed and a large part of the 'dark' conductance of the undried cell to the presence of a film of water in parallel with the selenium between the electrodes, and our observations agree quantitatively with this assumption.

We have also obtained some evidence of the existence of a much more transient polarisation in the desiccated cell, leading to a difference of conductance according to whether alternating or direct current is used, but this work is, for the present, incomplete. What has been established is that quite apart from the question of current alternation, the sensitivity of certain selenium cells, and probably of others, can be greatly increased by the simple process of thorough drying. The record of our work on this subject has been completed for publication and will, it is hoped, appear shortly.

Luminous Night Clouds.

DR. G. M. B. DOBSON, in his recent Halley lecture on, "The Uppermost Regions of the Earth's Atmosphere," makes mention of the phenomenon of 'luminous clouds' (NATURE, May 15, 1926, vol. 117, p. 697).

These clouds, discovered in 1885 by Prof. Ceraski, Moscow, may be observed in northern latitudes,

FIG. 1.—Luminous night clouds on August 8-9, 1925, 22 h. 47 m. U.T. Exposure 2 min.

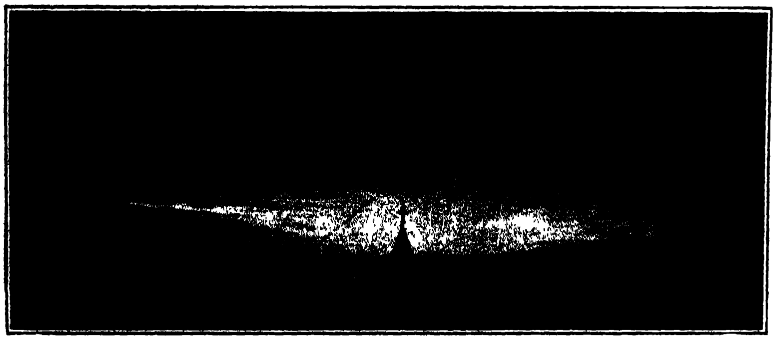

FIG. 2.—Luminous night clouds on August 8-9, 1925, 23 h. 29.5 m. U.T. Exposure 3 min

50°-60°, during the summer period, between the middle of May and the middle of August; in the southern hemisphere they are observed from November to February.

The 'luminous' clouds are rather like the 'cirri' in appearance, but they seem to gleam on the background of the segment of the dawn, whereas the common 'cirri' appear dimmed and dark when seen against the sky at dawn. The characteristic feature of luminous clouds appears to be, as indicated by O. Jesse, their unchangeable altitude over the earth's surface; on the average about 82 km. It is interesting to note that the Heaviside layer, which plays such an important part in radio telegraphy, is at the same height of 80 km.; moreover, according to Trowbridge (*Astrophys. Journal*, 1907), the tails of meteors are generally also observed at this same height (87 km.). These facts indicate peculiar properties for the layer lying at an altitude of 80-85 km. above the earth's surface; it seems possible that all phenomena observed at this height are closely connected with one another.

Our knowledge of luminous clouds is very incomplete and we have no satisfactory theory relating to their origin. The hypothesis of volcanic origin, maintained for some time after the first observations of luminous clouds in connexion with the eruption of Krakatao in 1883, had to be rejected, these clouds being observed almost every year, and independently of volcanic eruptions.

Lately (*Met. Zeitschrift*, Oct. 1925) a theory proposed by A. Wegener regards luminous clouds as being due to condensation of normal water vapour; this theory, however, has also met with many objections (*Met. Zeit.*, Mar. 1926.)

Luminous clouds, after being a vary rare phenomenon for a certain period of time, were again frequently observed during recent years. They were observed in Russia in 1916-19-20-22-23-24, and 1925; on the night of August 8-9, 1925, I succeeded in obtaining six photographs of these clouds from Leningrad at the Astronomical Observatory of the Russian Amateur Society for the Study of the Universe (Mirovédénïé) and the Scientific Institute of P. F. Leshaft (Figs. 1 and 2). The measurements of the photographs showed that the clouds, having started from a point 13° to the east from north, moved with the velocity of 230 metres a second to the south-south-west.

A detailed account of these observations will shortly appear in the Journal *Mirovédénïé* (vol. 15, No. 2, 1926).

We consider observations of luminous clouds to be extremely valuable and should feel greatly obliged if any one would send to us duplicates of observations made either at the present time or relating to any other epoch. Photographs would be especially valuable.

Guidance as to methods of making these observations may be found in an article by W. Foerster and O. Jesse in *Astron. Nachrichten*, Bd. 130, 1892.

Magnetic Properties of Single Crystals of Iron.

REFERRING to the letter in NATURE for May 29, p. 753, by Messrs. Honda, Kaya and Masuyama, it will be noted that Fig. 1, showing the magnetisation curve for a large crystal of iron, indicates the occurrence of definite and distinct steps in the magnetisation curve, but no explanation is foreshadowed.

In the *Journal of the Institution of Electrical Engineers* for September 1920, vol. 58, p. 832, I suggested that such steps were likely to be found in the magnetisation of iron crystals on the probability that more than one configuration would be involved before saturation was reached. Any such steps would be hidden in commercial iron owing to the irregular arrangement of crystals and the resultant overlapping in their individual characteristics, but in an individual crystal with a wholly symmetrical arrangement one would expect a relatively sudden change of pattern falling into a different space-lattice.

It would be interesting now to have an X-ray examination made of the crystal to ascertain the configuration corresponding to each stage of the magnetisation curve.

Climatic Changes during Geological Times.

By C. E. P. Brooks.

I. Glacial and Genial Periods.

After the primary discovery of geologists that the various strata of rocks exposed at the earth's surface could be arranged in chronological order, and that when so arranged they represented a sequence covering a very long period of time, the most striking result of their investigations has concerned the great variations of climate which all parts of the earth's surface have passed through. Coral reefs have extended into the British Isles and central Europe, and evergreens have flourished beyond the Arctic Circle. At the other extreme, large areas now enjoying a temperate or even tropical climate were covered by thick ice-sheets.

The evidence for all these changes is now so abundant that the general facts can no longer be questioned, though there are still differences in the interpretation of details. Thanks to this patient accumulation of evidence, we are now well acquainted with the climatic history of most parts of the earth's surface. Only the very oldest strata, the Archæan, composed of gneisses and similar rocks, are so altered that they give practically no information as to the climate prevailing when they were formed. At one time they were believed to be remnants of the earth's original crust, born in fire, but although the uranium-lead and thorium-lead ratios show that, according to the usual method of computation, some of these rocks are so much as 1600 million years old, the astronomical calculations summed up by Harold Jeffreys point to the age of the solar system as being very much greater still. Hence it is very improbable that any parts of the original crust of the earth still remain accessible.

The sedimentary rocks formed in the succeeding Proterozoic era are in many localities sufficiently unaltered to indicate the conditions under which they were laid down. During the greater part of this era the prevailing deposits were sandstones, such as the thick Torridonian Sandstone of Scotland, and limestones, but in many widely separated areas glacial deposits have been found—near Adelaide in Australia, in the Himalayas, South Africa, the United States, the head of the Yang-tse River in China, and perhaps also in Scotland and the Varangerfjord in Norway. The glacial phenomena at the latter site are very fine; they may be of any age from Proterozoic to Permian, but are most probably Lower or Middle Cambrian. The succession of events is best shown in Australia, where ancient boulder-clays or 'tillites' have been found on two horizons separated by 9000 feet of conformable strata. The later of these two tillites occurs probably just below the base of the lower Cambrian. Two glacial horizons, one probably just pre-Cambrian and the other much older, have also been recognised in South Africa, and possibly in the United States and India.

The Palæozoic was thus ushered in by an ice-age, but by the Middle Cambrian all traces of glaciation, with the possible exception of the Norwegian, seem to have disappeared, and by the Upper Cambrian at least mild climates had developed in all parts of the world. The temperature was not the same in all latitudes; for example, the Archæocyathinæ, which are fully developed in Australia, are dwarfed and crippled in the Antarctic, but the zonal differences were less than at present. The Ordovician period was one of prolonged warmth; in the Silurian this general warmth continued, and corals spread into all latitudes, though in the Arctic only isolated dwarfed forms occur. The Silurian also gives us some evidence of the development of desert climates, while in south-east Alaska, and possibly in Tasmania, there are traces of ice action. In the Lower Devonian the faunal zones became more accentuated, and there is evidence of ice action at Table Mountain in South Africa and probably also in the Falkland Islands. In the Upper Devonian, however, the general warmth appears to have returned, and in the Old Red Sandstone extending from England to the Baltic States we have evidence of a widespread arid region, which Walther compares with the interior of Australia or with the Trans-Caspian desert. The prevailing warmth continued into the Lower and Middle Carboniferous, when thick coral reefs were formed in middle latitudes and a cosmopolitan flora spread over the greater part of the land surfaces, but in the Upper Carboniferous the ice-sheets returned over very wide areas.

This ice-age is generally termed the 'Permo-Carboniferous,' because when its remains were first discovered they were believed to fall mainly at the junction of these two periods. It now appears that the ice reached its greatest development in the Upper Carboniferous, when the ice-covered area was probably greater than at any other time in the earth's history. The most remarkable feature of this glaciation is the distribution of the ice-sheets—a large part of Australia, South Africa, India, eastern South America from southern Brazil to the Falkland Islands. This immense area, much of which is now within the tropics, was covered, not by local valley glaciers, but by immense regional ice-sheets. The striæ indicate that the ice moved southwards in Africa, but northwards in India, *i.e.* away from the equator, but in Australia the centre of dispersal lay to the south-west of Tasmania. Farther north there are some rather doubtful glacial deposits in Europe—Germany, France and Holland—and a large amount of quite definite evidence of glaciation in North America, where the glaciers appear to have attained a considerable size and to have reached the sea. The most interesting glacial deposits in North America, the 'varve' clays associated with the Squantum tillites, will be referred to later. No Carboniferous glacial deposits have yet been discovered in the Antarctic.

Apparently contemporaneous with the ice-sheets was the rich flora of the Coal Measures in North America, Europe and Asia, which developed from the cosmopolitan flora of the Middle Carboniferous, but in Australia, India and South Africa a new flora of hardier appearance developed above the glacial deposits—the Glossopteris flora.

In the Upper Permian the climate again became generally warm and dry, and this initiated a long period of genial climate which persisted with only minor interruptions throughout the Mesozoic and the greater part of the Tertiary. There was floating ice in the English chalk seas and in Australia in the Cretaceous, and Alpine glaciation in the Antarctic and

in the San Juan Mountains of Colorado in the Eocene, and perhaps in the Italian Alps in the Miocene, but the general impression given by the Jurassic coral reefs of Europe and the Upper Eocene Arctic flora is one of slight differences of temperature between different latitudes and warm ocean currents penetrating into the neighbourhood of the poles.

During the Pliocene the temperature began to fall rapidly, and it is probable that quite early in this period the Antarctic ice reached the sea, while a boreal fauna developed in the Arctic Ocean which spread out into the Atlantic, and early in the Quaternary penetrated into the Mediterranean. During the latter period glaciers formed on the mountain ranges in all parts of the world, developing into great ice-sheets in the north temperate zone, where there were four main advances of the ice—the well-known Gunz, Mindel, Riss and Wurm stages of Penck and Brückner's classification. Since the maximum of the Wurm there have been several minor oscillations, passing gradually into the present climate.

The outstanding features of this history are the alternation of glacial and genial periods and the association of glaciation with mountain-building, of warmth with periods of rest. The Lower Proterozoic glaciation was associated with great outpourings of lava, the Late Proterozoic-Early Cambrian glaciation coincided with a period of disturbance, the Upper Carboniferous glaciation followed the Hercynian folding, and the Quaternary glaciation followed the culmination of the Alpine folding. Minor periods of unrest, such as those of the Silurian or Cretaceous, were followed by minor deteriorations of climate. This orogenic-climatic cycle becomes more obvious when the dates are considered. The Quaternary glaciation was an affair of yesterday. The radio-active clock (according to the usual basis of calculation) gives the age of the Upper Carboniferous as 260 million years, and the base of the Cambrian as 500 million years. The interval between the two Proterozoic glaciations has not been defined exactly, but a reasonable estimate would be 200-300 million years. Thus each cycle of the geological seasons seems to have run its course in about 250 million years, giving a regular sequence which has been termed the "rhythm of geological time."

Before the causes of this grand climatic cycle can be discussed, however, the possibility has to be considered that the fluctuations were more apparent than real. In any region, such as Europe, the climatic sequence can be expressed in terms of variations of apparent latitude. This obvious fact has led to several theories of 'pole-wandering' and 'continental drift'—Simroth, Kreichgauer, and finally, the very complete and far-reaching theory of A. Wegener.[1] Wegener's work seems at first sight unassailable. The earth's surface is at present divided into a number of climatic belts—an equatorial rain-forest belt, two sub-tropical dry belts, two temperate rain belts, and finally two polar glacial caps. Now consider the climatic variations of western Europe. In the Upper Carboniferous there are the coal-measures—apparently the remains of an equatorial rain forest. In the Triassic there are desert sandstones—remains of the sub-tropical dry belt. During succeeding geological periods Europe passed successively through the warm temperate and the cold temperate belts until in the Quaternary it entered the polar glacial cap. Now go back to the Upper Carboniferous. If regions now in latitude 50° N. were on the equator, the south pole must have lain in some point now in 40° S. While Europe was much warmer than it is now, a large part of the southern hemisphere must have been much colder, and in fact a large part of the southern hemisphere now enjoying warm temperate or sub-tropical climates was then glaciated.

So long, however, as the continents remained in their present positions relative to each other, some parts of the southern glaciated region must fall in low latitudes no matter where the south pole is placed. Wegener gets over this difficulty in two ways. First, he considers that the relative positions of the continents have not remained the same. Continents are composed of masses of relatively light rock (sial), embedded in heavier rock (sima) which under long-continued pressure acts as a viscous fluid. Hence under the continuous action of any horizontally directed force the continents will drift through the sima. The east coast of America fits so neatly into the west coast of Europe and Africa that there is good warrant for believing that the two were formerly united and have recently drifted apart; there is some geological and biological evidence in support of this view. Similarly, though on less plausible grounds, Wegener effects a *rapprochement* of Africa, India, Australia and the Antarctic continent, the whole forming in Carboniferous times a compact continent or 'Pangæa,' centred near the south pole. But even this is not enough; parts of the glaciated area of Pangæa extended into temperate latitudes, and Wegener further supposes that the south pole described a wide curve through this primitive continent, so that different parts of the land area were glaciated at different times.

Wegener accounts for the long periods in which there is no evidence of ice action anywhere on the earth by supposing that during these periods the poles lay near the centres of extensive oceans, while during the glacial periods the poles lay near or over the land. In the Miocene the north pole is placed over Alaska, whence it moved eastwards across North America and Greenland to the neighbourhood of Spitsbergen. Thus the 'Quaternary' glaciation of America is older than that of Europe. The succession of glacial and interglacial periods is accounted for by Köppen[2] on astronomical grounds.

The whole work is wonderfully ingenious, and it has been accepted by many geologists. There are, however, a number of very serious objections to it. The forces which Wegener postulates to move the continents are twofold—a tidal force acting from east to west, which is indefinite but may be large, and a very small drift towards the equator which is common to all floating bodies. H. Jeffreys[3] considers that while the deeper layers of the sima are viscous, the surface layers are too rigid to allow these small forces to act. Joly's recent theory of the cyclic melting and solidifying of the sima[4] may provide an escape from this objection, and

[1] Wegener, Alfred, "The Origin of Continents and Oceans." Transl. by J. G. A. Skerl. London, 1924.

[3] Jeffreys, Harold, "The Earth; its Origin, History and Physical Constitution." Cambridge, 1924.

[4] Joly, John, "The Surface-history of the Earth." Oxford, 1925.

we may perhaps grant the possibility of east-west movement for which there is some geophysical evidence. But the "flight from the poles" is another matter, and in fact, according to Wegener's reconstructions, during a large part of geological time the main mass of land in the northern hemisphere was moving, not *from*, but *towards* the north pole. The evidence for these movements is entirely palæoclimatic, and needs to be very convincing to support such far-reaching deductions. Is it convincing? Leverett's comparative studies of European and North American glacial deposits do not bear out the assumption that the main part of the American glaciation is far older than the European. According to W. H. Dall the Miocene glaciation of Alaska is a myth, the main glaciation of that country having occurred in the Quaternary. The mild polar climates of the Upper Eocene cannot be accounted for by movements of the poles, since Berry has shown that a flora allied to the present temperate flora completely surrounded the north pole in high latitudes, forming a ring out of which it is impossible to bring the pole in any direction. The desert deposits of the Mesozoic are practically limited to the latitudes in which deserts are found at present. Wegener's reconstructions do not account at all for the climatic sequence in the Antarctic, as recently set out by Wright and Priestley.[5] There remains the Upper Carboniferous period.

[5] British (*Terra Nova*) Antarctic Expedition, 1910–1913, "Glaciology," by C. S. Wright and R. F. Priestley. London, 1922.

Most meteorologists would say that the development of extensive ice-sheets reaching sea-level within the tropics is inconceivable, and that for the Upper Carboniferous Wegener's theory offers the only possible solution. The succession of glaciations in different continents following a moving pole is not tenable in the light of recent geological work, which seems to demonstrate the approximate synchronism of the glacial maximum in all countries, but this scarcely affects the main problem. A more serious objection is the Upper Carboniferous glaciation of North America, which Wegener's reconstruction places on the equator. Evidence has been found that in Oklahoma, Arkansas, Massachusetts, Nova Scotia and perhaps in other regions also, powerful glaciers reached the sea, and icebergs or heavy shore ice transported large boulders fifty miles or more from their original source. The best development is seen in the Squantum beds near Boston, where, in addition to thick tillites, there are seasonally banded clays which are similar in all respects to the 'varve' clays formed during the retreat of the Quaternary ice-sheets in Sweden, Finland and North America. The glacial nature of these beds appears to be incontrovertible, and the well-marked seasonal banding appears to be incompatible with their formation on the equator. Whether Wegener's theory is adopted or not, the climatological problem presented by ice reaching sea-level within the tropics still remains to be solved.

(*To be continued.*)

On the Rare Earths.

THE group of about sixteen elements the oxides of which are popularly known as 'rare earths' are characterised by an exceedingly close relationship in their chemical and physical properties—a relationship which, in its intimacy, is not paralleled by any other group of elements. In consequence of this fact, the task of isolating the individual members of the group has been one of quite exceptional difficulty. Until recent years, practically every reported discovery of a new element of the group was proved, by later searching investigation, to be not one element, but two or more. In addition to this difficulty has been that of distinguishing an alleged new element from some other previously discovered element, with the result that one and the same element was discovered over and over again, each discoverer giving it a separate name. Hence, the chemistry and the nomenclature of the rare earths were for many years in a state of almost hopeless confusion from which they have emerged only during the present century, and particularly in the last decade.

The history of the discovery of the rare earths goes back to 1794 when Gadolin discovered the yttrium earths, out of which a considerable number of separate elements have since been identified. By the discovery of ytterbium and cassiopeium (or lutecium) by Auer von Welsbach in 1906, it was thought that the whole of the rare earths had been discovered, and it was not until the development of the atomic number rule by Moseley that it was found that a space in the series, corresponding to an element with an atomic number of 61, was vacant. There is now fairly conclusive evidence that, after a great amount of work by various investigators, including an exhaustive and negative examination of rare earth fractions by Prandtl and Grimm extending over a year, this element has been definitely identified by the use of the X-ray spectrum. There is also good reason for supposing that with the discovery of illinium, the name given to the supposed new element, the whole of the rare earth elements have been found and identified.

The term 'rare' as applied to these elements is relevant only in the case of a small minority of them. Cerium, believed to be the most abundant, is considered to be little, if any, scarcer than nickel, and many of the others are far from being scarce, even if concentrations of them are not common. On the other hand, a few of the elements appear to be among the rarest known, and this appears to be particularly true of erbium, and the element 61, which has so long eluded the searchers for it and even yet has not been found in measurable quantity.

The primary occurrences of the rare earth minerals in Nature are confined mainly to pegmatite dykes or pegmatitic rocks, considered to have been formed during the last phases of crystallisation and differentiation of an intrusive magma, that is to say, to the phase following acid rock formation. But rare earth minerals are usually not present in important concentrations in the primary rock formations, and it is only by the denudation of the containing rocks and the natural concentration of the relatively heavy minerals set free that accumulations representing any appreciable quantity of the material are formed.

The main source of the rare earths, so far, has been

monazite sands found in considerable accumulations in Travancore in India, Bahia State in Brazil, as well as in Ceylon and a number of other places in the world. The composition of monazite sand is complex, but essentially it consists of the phosphates of cerium and lanthanum. But the economic value of the sands depends on the percentage content of thorium minerals which are now used so extensively in the manufacture of the incandescent gas mantle. The cerium content has some economic value, being also used in small proportion in the incandescent mantle industry, and also for the manufacture of ferro-cerium, well known in the form of the sparking type of lighter.

The following are partial analyses of two samples of monazite sand, one from Travancore and the other from Bahia:

	Travancore. Per cent.	Bahia Per cent
Thoria	9·43	6·50
Ceria earths	31·90	61·40
Lanthanum earths	28·00	
Yttria earths	0·46	0·70

The yttrium earths have been used in the manufacture of the incandescent parts of Nernst lamps, but for most of the other rare earths no industrial outlet has been found. In some quarters it has been suggested that certain of them may prove valuable as catalysts.

With reference to the close association of the rare earths in Nature, it is obvious that since the chemist finds so much difficulty in separating these by methods of great refinement, the crude large-scale metallurgical processes of Nature must tend to segregate them in groups rather than separately. The rare earth group is scarcely unique in this respect; the platinum group of metals is a more or less parallel example where the so-called native platinum may be, and often is, a complex alloy of platinum, iridium, osmium, palladium, ruthenium and other metals. All of these metals possess closely related physical and chemical properties which lead to their segregation in the basic and ultra-basic differentiations of an intrusive magma. The rare earth minerals, however, mainly associate themselves with silicious and aluminous magmas.

The conception of atomic numbers and the history of the discovery that X-ray spectra could be used in the identification of previously unknown elements have formed the subjects of numerous articles and communications in the scientific and philosophical press and need only be briefly mentioned here. The names associated with these discoveries include, among others, those of Laue, W. H. and W. L. Bragg, and Moseley, to all of whom great credit is due for their respective parts. Moseley's work in connexion with the development of the atomic number rule has been especially valuable. In the field of the rare earths, the determination of the atomic numbers has revealed definitely the possible number of distinct chemical elements. Between barium with an atomic number of 56 and tantalum with an atomic number of 73 there is room for sixteen elements. Prior to 1923 it was possible to speak of only fourteen of these elements as definitely known, but with the discovery of hafnium with an atomic number of 72 by Coster and Hevesy by means of the X-ray spectra, and the later discovery by Prof. B. S. Hopkins and his associates of what seems to be element No. 61, the sequence from 56 to 73 is complete and justifies the claim that all the rare earths have been discovered. The X-ray method of investigation also leaves no room for assuming that the list of rare earth elements contains duplicated cases, and that the same element may be regarded as two distinct elements under different names. The indications obtained by that method are open to one interpretation only, and those characteristic of a given element are distinguished without difficulty and beyond reasonable doubt.

From its simplicity, ease and rapidity of the experimental examination, the determination of the X-ray spectrum is becoming of the greatest importance in the investigation of particular elements in a mixture, and in the control of separations; it will most probably, in a large degree, if not entirely, replace the much more complicated and troublesome examination of the light emission spectrum. Not only are elements identifiable by this method with a rapidity and certainty which far surpass those of other methods, but a comparison of the densities of the lines with that of the lines given by a known quantity of a foreign element will give approximate quantitative results.

The method of using the apparatus presents no difficulty. The apparatus is arranged in much the same way as an ordinary spectrometer; the incident light is replaced by the beam of X-rays from the material under examination, which forms the anti-cathode, in a vacuum tube. The diffraction grating is replaced by the crystal slice, and the telescope and eyepiece (or photographic plate) by an ionisation chamber by which the intensity of the reflected beam may be measured.

Television.

THE possibility of 'seeing by telegraph' was fully recognised many years ago. The discovery that the electric resistance of selenium varied with the intensity of the light falling on it suggested to Professors Ayrton and Perry, amongst others, that the method was theoretically feasible. It was soon found out that selenium failed to respond quickly enough to the rapid changes in light intensity necessary for television, and it was not until the photo-electric cell had been perfected that inventors seriously attempted to solve the problem. The analogous problem of sending photographs and pictures by telephone wires or by radio waves, or by both these methods, we can consider as solved. It is now done commercially. Doubtless great improvements in the method will be introduced, and before very long every one will accept it as a commonplace operation and cease to regard it as wonderful.

The problem of television, however, is an immensely more complicated one, and even the most optimistic of scientific men had begun to think that it would be

many years before the first glimmering of a practical method would be developed. We were therefore agreeably surprised on making a visit to Mr. J. L. Baird, at Motograph House in Upper St. Martin's Lane, London, W.C., to find that he had installed there a transmitter and a receiver which prove that he has made great progress in solving the problem. We saw the transmission by television of living human faces, the proper gradation of light and shade, and all movements of the head, of the lips and mouth and of a cigarette and its smoke were faithfully portrayed on a screen in the theatre, the transmitter being in a room in the top of the building. Naturally the results are far from perfect. The image cannot be compared with that produced by a good kinematograph film. The likeness, however, was unmistakable and all the motions are reproduced with absolute fidelity.

The general principle utilised by Mr. Baird is not difficult to understand. The image of the object to be transmitted is made to traverse a cell sensitive to light. This cell modulates an electric current. When the light on the cell is intense the current is large and when the cell is in shadow it is weak. At the receiving station the current controls a source of light which traverses a ground glass screen which moves in exact synchronism with the image at the transmitter. The spot of light is therefore bright when the light on the transmitter is intense and dark when it is in shadow. The light from the image moves over the screen about ten times a second. Hence, owing to the persistence of vision, a complete image is obtained.

Just as in the early kinematograph films, there is a constant flicker, but this will doubtless be got rid of in whole or in part in the new Baird 'televisor.' This is the first time we have seen real television, and, so far as we know, Mr. Baird is the first to have accomplished this marvellous feat. He had the first inkling of the method two years ago when he successfully transmitted shadows by electricity. We were told that a similar method of transmitting shadows has been independently devised in America. But his present method is as superior to the shadow method as a photograph is to a skiagraph.

It is natural that Mr. Baird and his partner, Capt. Hutchinson, should contemplate a great future for television. They are taking steps in the direction of having a broadcasting system of television for London. Every possessor of a 'televisor' will be in a position to see on his screen the performers in operas and plays as well as hearing them. They expect to make a start in this new system of broadcasting next year. The new discovery will in no way interfere with the ordinary British broadcasting. The Post Office officials, seeing the probable advent of a new British industry, regard the scheme with benevolent neutrality.

Those of us who remember the advent of the telephone in 1876, and remember also how little its importance was then realised, will hesitate to criticise this new invention. There is endless scope for improvement. Mr. Baird, who, like Graham Bell, is a Scotchman, has been so extraordinarily and so rapidly successful in the past that we have great hopes that he will soon perfect his invention to the commercial stage. We wish him every success.

A. R.

Solar Surveys.

OUR Supplement this week will be read with great interest by specialists in solar research, and also by a considerable number of other readers to whom Dr. Hale's name is closely associated with the Mount Wilson Observatory and the progress of astrophysics. Since 1923 Dr. Hale has been engaged in perfecting an instrument for *visual* observation of the sun in monochromatic light; and the spectrohelioscope, as he calls it, is now permanently installed at his new solar laboratory at Pasadena. The recent increase of solar activity shown by sunspots, flocculi, and prominences has afforded him ample opportunity for testing the capabilities of the instrument. Its performance appears to have exceeded all expectations, and a rich harvest of results may be anticipated, especially with respect to observations of the sun's upper atmosphere and the hydrogen vortices registered in the light of $H\alpha$. These hydrogen vortices, which have been studied almost exclusively since their discovery in 1908 by Dr. Hale and his colleagues at Mount Wilson, are bound up with the problem of the nature of sunspots and their unexplained reversal of magnetic polarity at each spot minimum. The development of the spectrohelioscope, its uses as a powerful instrument of research, and a survey of results obtained to date are reviewed by him in this week's Supplement.

It is a matter for comment that the development of the spectrohelioscope was delayed by slight circumstances for more than fifty years. As Dr. Hale reminds us, the pioneers of solar spectroscopy, such as Jannsen, Lockyer, and Young, were fully aware of the principle involved; Young, indeed, constructed a spectrohelioscope for seeing the prominences at the sun's limb, but it was never applied for observing phenomena on the disc. The wide slit method for prominence work, introduced in the meantime by Zöllner and Huggins, was so successful that a narrow oscillating slit—one of the essentials of the spectrohelioscope—was abandoned, and later experiments, then directed to *photographic* registration in monochromatic light, resulted in the spectroheliograph by Hale and the velocity spectrograph by Deslandres. Thus the need for a visual survey of the sun's atmosphere projected against the disc persisted until the construction of Dr. Hale's spectrohelioscope.

Of the many interesting observations, described and beautifully illustrated in Dr. Hale's characteristic manner, attention may be directed to those by which the observer views in rapid succession the ascending and descending portions of the same hydrogen flocculus and the sunspots which may happen to lie beneath. Dr. Hale's enthusiasm and inventive skill are now being directed to the making of a modified form of spectrohelioscope which he hopes may be within the reach of amateurs. If these hopes are realised, the chances of detecting the exact moments of critical outbursts on the sun will, as he says, be greatly multiplied, and such observations should prove most valuable in determining the true relationships between solar eruptions and terrestrial magnetic storms.

Obituary.

MR. J. J. FLETCHER.

BY the death on May 15, at the age of seventy-six years, of Mr. J. J. Fletcher, who for thirty-three years was secretary of the Linnean Society of New South Wales, Australia has lost one of the ablest and most sincere as well as one of the most beloved of her scientific workers. He was one of the first two Australians to take a science degree at the University of London, and during his visit to England he came under the influence of the late Prof. Francis Balfour at Cambridge, an experience that exercised a lasting influence upon his work and ideals. For the last forty years his life has been devoted to the Linnean Society of New South Wales, and its work bears the imprint of his fine character in the standard which has been maintained throughout all these years. He joined the Society in 1881, and at the time of his death was the second oldest member. During the course of his tenure of the secretaryship of the Linnean Society he also controlled the general management of the Society's affairs and edited the *Proceedings*. But this list of duties gives no adequate idea of the extent of his services to biology in Australia. He took his work as editor very seriously, and few of the contributors to its *Proceedings* failed to receive very material help from him in the lucid presentation of their results and in completing their bibliographical references. He was as modest and tactful as he was helpful.

Since 1881 Mr. Fletcher contributed about thirty-five important papers to the Linnean Society, including twenty-seven zoological papers, dealing largely with kangaroos, earth-worms, and frogs. He was one of the first to investigate closely the embryology of the marsupials, for which purpose he made many expeditions to collect material. His knowledge of the Australian amphibia was unsurpassed. During later years he contributed some botanical papers dealing with phases of eucalyptus and acacia seedlings. The account of his careful study of the families Loranthaceæ and Proteaceæ has unfortunately not been completed. Much of the valuable information he possessed concerning these plants has gone with him, for he was unable to find time to prepare for publication more than a very small percentage of his valuable knowledge.

On his retirement from the position of secretary of the Linnean Society of New South Wales Mr. Fletcher was made president, occupying the chair during the years 1919 and 1920, and his numerous friends presented his portrait to the Society, with a request that it be hung in the Society's hall in recognition of the great work he had so successfully carried out. He was president of the Biology Section at the Melbourne meeting of the Australasian Association for the Advancement of Science in 1900. In 1921 he was honoured by the Royal Society of New South Wales as the recipient of the Clarke Medal, "awarded from time to time for meritorious contributions to the geology, mineralogy, or natural history of Australia." At the time of his death he was a member of the council of the Linnean Society of New South Wales and a trustee of the Australian Museum.

PROF. C. J. LINTNER.

BIOCHEMISTRY of fermentation has sustained a loss by the death of Geheimer Hofrat Prof. C. J. Lintner, who died at the age of seventy years on April 8 after a long and severe illness. The deceased was the son of Dr. Carl (afterwards Hofrat) Lintner, director of what is now the Agricultural High School, Weihenstephan, who was also the founder of the Scientific Station for Brewing at Munich.

Lintner graduated at Munich in 1882 under Adolf v. Baeyer. After spending some years of work in connexion with agricultural chemistry, he became assistant at the Institut für Garungsgewerbe, Berlin, after which he acted as assistant to Soxhlet at the Landwirtschaftliche Zentralversuchsstation, Munich. In 1888 he was appointed to a chair of technical chemistry at the Technical High School, Munich, becoming "ordentlicher" professor in 1896, his work dealing more particularly with fermentation chemistry.

As regards his researches, Lintner will be chiefly remembered by his work on enzymes, more especially the amylases, and on the transformation products of starch. In 1891 he claimed that one of the products obtained from starch paste when treated with malt amylase is an isomaltose. The existence of this alleged substance was denied by Brown and Morris in 1895, and doubt was thrown on its existence by Ling and Baker in the same year. In 1897, however, Ling and Baker obtained some positive evidence of the truth of Lintner's views, whilst in 1902 Syniewski confirmed the existence of isomaltose and re-named it dextrinose. The existence of the sugar was definitely established by Ling and Nanji in 1923.

Lintner was a man of extreme amiability, and his generous and modest character won for him the esteem of his colleagues and pupils. A. R. L.

PROF. FRANZ VON SOXHLET, emeritus professor of agricultural chemistry at the Technical High School in Munich, died early in May at the age of seventy-eight years. Soxhlet was a native of Brünn, and was appointed to Munich in 1879, where he became director of the central agricultural research station. He was well known for his work on the sterilisation of milk. He did not long survive his distinguished assistant Lintner, whose death was recorded in our issue of June 12 and is referred to again above.

WE regret to announce the following deaths:

Prof. F. N. Cole, professor of mathematics in Columbia University since 1895 and secretary for many years of the American Mathematical Society, distinguished for his work on the theory of groups and the theory of numbers, on May 26, aged sixty-four years.

Dr. Henry Skinner, president in 1909 of the American Entomological Society, who was known for his work on Lepidoptera, on May 30, aged sixty-five years.

Prof. Sidney Irving Smith, professor emeritus of comparative anatomy in the Sheffield Scientific School of Yale University and a member of the National Academy of Sciences since 1884, known for his work on invertebrates, notably crustaceans, on May 7, aged eighty-three years.

News and Views.

AN extraordinary general assembly of the International Research Council was held at Brussels on Tuesday, June 29. After agreeing unanimously, on the motion of the Executive Committee, to omit from the statutes words which have limited membership to allies and neutrals, the following motion proposed by the president of the Royal Society was passed unanimously. "That this meeting of the extraordinary general assembly of the International Research Council decides to invite Germany, Austria, Hungary and Bulgaria to join the International Research Council and the Unions attached to it and, in doing so, to indicate the institution which will act as adhering body."

THE second reading of the Public Health (Smoke Abatement) Bill was moved in the House of Commons last week by Mr. Chamberlain. So far as it goes, the Bill is a step in the right direction. The provisions of the 1875 Act are amended to include other kinds of smoke besides black smoke; temporary exemption is to be allowed for certain processes for the present; the power of local authorities to regulate the emission of noxious smoke is to be extended. No provision is, however, made for reducing smoke from private dwelling-houses, which in many places are the greatest sinners. While the time may not be ripe for compulsory prevention of smoke from private houses, this does not appear sufficient reason for not making some provision to bring about improvement by encouragement instead of penalty, such as by empowering local authorities to make a rebate on the rates for users of smokeless methods only. In the debate, several speakers referred to the advantage of the open fire—a pleasant radiant heat and plenty of ventilation. If these can be combined with smokelessness it will be the best solution. There is in the Bill no provision for standards of permissible smoke emission, and it is doubtful if much useful result will follow until such are set up. As Mr. Chamberlain admits, it is rather on the administration that we shall have to rely for improvement of the conditions of the atmosphere, a reliance scarcely justified by our past experience. It would give more hope of improvement if the Bill empowered the Minister of Health to fix standards of industrial smoke emission from time to time; but the necessary preliminary must be the finding of a reasonably accurate method of measurement. The natural sequence would then be: (*a*) Find a suitable method of measuring smoke from chimneys; (*b*) fixed standards of emission based on (*a*); (*c*) enforce such standards legally.

THE Office d'Information scientifique et technique of Paris, the initiation of which was noted in our issue for June 12, has favoured us with copies of two recent news bulletins, which are interesting to compare with similar issues of the allied Science Service in Washington. The French material has been well selected, and is of real scientific interest; the language is plain and the treatment straightforward, but its somewhat educational tone raises a doubt as to whether the presentation is sufficiently attractive to appeal to editors and readers of the popular Press; it may be, however, that the intellectual standard in France is higher than elsewhere. In the United States and England, it is the practice to attract the reader by one or more glaring headlines, to convey the gist of the information (which should contain news) in a short initial paragraph, and then to proceed with details and embellishment. The French procedure, as displayed in these bulletins, is more logical: the headlines are distinctly sober and lacking in 'pep'; the article begins with an explanatory or historical preamble, and the news is reserved for a later stage. Although this method will be preferred by the student, it is less effective in attracting the lay reader than the more sensational style of approach.

THE 'news' element of the bulletins is not strongly represented in the specimens before us, and in a few cases, for example, the articles on telegraphic reception and the nature of X-rays, the explanations given may convey little to the uninitiated. In about one-half of the items the information comes from the United States, and the remainder from France; when the Service gets better under way one may expect material from other countries to be included. The news appears to have been culled mainly from periodical literature—which must always constitute an important source—but it is to be hoped that first-hand news obtained from research workers and inventors will later become available; in this respect the American Service has been singularly successful. It is of happy augury that the French organisation is starting with high ideals. it will not try to serve both science and mammon; commercial profit is outside its scope and there will be no traffic with the advertiser; and it will preserve a rigid independence of all parties, groups and factions. Its sole aim is the prompt diffusion of scientific and technical knowledge in a way that will neither 'mystify the crowd' nor promote sophistry and error by over-indulgence in 'purple patches.'

WE are glad to direct attention to the letter on p. 10 of this issue referring to the proposed widening of the activities of the Universities' Library for Central Europe. The original letter in NATURE of May 22 relating to the disposal of scientific journals brought responses from scientific institutions, research workers and others, from which it was evident, as we suspected, that although of no commercial value, back numbers of scientific journals and similar publications would be of very real use if they could be distributed in the right quarters. Such a central distributing organisation already exists in the Universities' Library, and we trust that sufficient support will quickly be forthcoming to enable it to undertake the new function which it is now proposing to assume.

THE first number of the *British Journal of Psychical Research*, the editorial address of which is 16 Queens-

berry Place, South Kensington, S.W. 7, merits mention in this column owing to the claim made in a foreword by the editor that one of its objects is "to deal with ascertained facts in a strictly scientific manner." It is a fine ideal to start out with, but one very difficult of attainment, apparently, in this particular subject. The account of the "Model Psychic Laboratory" on pp. 11-20, with photographic illustrations, is the best article in the number. The laboratory in question is the National Laboratory of Psychical Research at Queensberry Place, and the article is very helpful in giving a clear idea of the arrangements and apparatus in use there. We note that future numbers will contain accounts of experiments with a young psychic known as Miss Stella C., whose portrait forms the frontispiece of this number. There is also a very full account of the first case of alleged mediumship which has come up for investigation before the officers of the Laboratory. This is dealt with by Mr. Harry Price under the title of "Pseudopsychic Manifestations due to Self-induced Hysteria." The conclusion that the phenomena were all due to evident hysteria appears to cover quite fully all the facts noted. The same author, in a shorter article entitled "A Plea for Accuracy," makes some very caustic comments on an article by an American investigator, who, in dealing with the problem of so-called psychic photography, makes the remark (in italics) that "*the plates never left my hand until the negative was developed in the dark room,*" but innocently publishes alongside this statement the resulting photograph, showing a "psychic extra" on a photograph of himself in which his hands are clearly visible, and therefore could not have been holding the plate! The editor having thus set a high standard, both of accuracy in his own articles and of very candid criticisms of inaccuracies in those of other journals, we may express the hope that future numbers will worthily uphold his ideals.

The Australasian Association for the Advancement of Science will hold its eighteenth meeting in Perth, Western Australia, during the week commencing Monday, August 23 next. Owing chiefly to the long and costly journey from other parts of Australasia, no previous meeting of the Association has been held in Perth; consequently Western Australia is making special efforts to secure a good attendance of members from other States and from New Zealand. Private hospitality in Perth during the meeting is being offered to all visiting members. The State Government has granted 1200*l.* towards defraying the cost of printing and publishing, and is giving free transit to visiting members over the W.A. Government Railways, whilst the Australian Commonwealth Government has granted for the Perth meeting the sum of 750*l.*, out of which travelling allowances will be made to members coming by the Transcontinental Railway. As the various countries bordering on the Indian Ocean have many scientific problems in common, the Perth local committee has sent invitations to representative scientific men in those countries to attend the meeting, hoping thus to make it an informal Indian Ocean Science Congress, and thereby to inaugurate closer intellectual co-operation amongst the Indian Ocean peoples. To anthropologists, botanists, geologists and zoologists, Western Australia offers features which are unique, even for Australia; and a series of excursions has been arranged to enable visitors to study these as well as the economic resources of the State in mining, agriculture, fruit-growing, forestry, etc.

The retiring president of the Association is Lieutenant-General Sir John Monash, whilst the president-elect is Prof. Edward H. Rennie, of the University of Adelaide, who has chosen as the title of his presidential address "The Chemical Exploitation, Past, Present and Future, of Australian Plants." The chairman of the local committee is the Hon. P. Collier, Premier of Western Australia. The presidents of sections and the titles of their addresses are as follow: *A* (*Astronomy, Mathematics, and Physics*), Prof. Kerr Grant, "Atomic Transformation"; *B* (*Chemistry*), Prof. James Kenner, "Some Aspects of the Problem of Molecular Structure"; *B* 2 (*Pharmacy*), Mr. A. T. S. Sissons, "The Indebtedness of Pharmacy to Organic Chemistry"; *C* (*Geology and Mineralogy*), Sir Douglas Mawson, "The Igneous Rocks of South Australia—a brief survey of present knowledge relating thereto"; *D* (*Zoology*), Prof. Launcelot Harrison, "The Composition and Origins of the Australian Fauna, with special reference to the Wegener Hypothesis"; *E* (*Geography and History*), Prof. Ernest Scott, "The Discoveries of the Western Australian Coast, with especial reference to Dampier and D'Entrecasteaux"; *F* (*Ethnology and Anthropology*), Prof. F. Wood Jones, "The Claims of the Australian Aboriginal"; *G* (*Social and Statistical Science*), Major L. F. Giblin, "Federation and Finance—an Examination of the Financial Relations of States to a Federal Commonwealth"; *H* (*Engineering and Architecture*), Sir John Sulman, "Town Planning", *I* (*Sanitary Science and Hygiene*), Mr. F. S. Hone; *J* (*Mental Science and Education*), Mr. P. Board, "Social and Economic Values in Education"; *K* (*Agriculture and Forestry*), Mr. C. E. Lane Poole, "Forestry and Land Settlement"; *L* (*Veterinary Science*), Prof. J. Douglas Stewart, "The Relationship of Veterinary Science to the Prosperity of the State"; *M* (*Botany*), Prof. A. J. Ewart, "Past and Future Development of Botanical Science"; *N* (*Physiology and Experimental Biology*), Prof. W. A. Osborne, "The Study of the Reflex." The hon. local secretaries for Western Australia are Mr. A. Gibb Maitland, Geological Survey, Perth, and Prof. N. T. M. Wilsmore, University, Perth, W.A.

At the invitation of the Gas, Light and Coke Company, a large and distinguished scientific audience assembled on June 24 in the Company's offices in Horseferry Road, Westminster, to hear Prof. W. A. Bone lecture on "New Experiments on the Combustion of Carbonic Oxide." The experiments described, and in many cases beautifully reproduced, form part of researches which Prof. Bone and his

collaborators have been carrying out during the past three years at the Imperial College of Science, South Kensington, aided by fellowships given by the Gas, Light and Coke Co. and Radiation, Ltd., and described in detail in recent numbers of the *Proceedings of the Royal Society* (*e.g.* in the issue for April 1, pp. 615-44, 1926 [A]). The outstanding result of this work is that, contrary to former belief, carbon monoxide will, under suitable conditions, combine with oxygen in the absence of moisture. Mixed in the volumetric ratio of 2 : 1, at atmospheric pressure, these gases ignite with increasing difficulty as they are progressively purified from water vapour, but even after six months' drying over phosphoric oxide, they can be exploded by means of a sufficiently powerful condenser discharge. The union is facilitated by increasing the original pressure of the gaseous mixture, although it appears to reach a limiting value of about 98 per cent.

PROF. BONE stated that spectrograms obtained on exploding carbon monoxide with air, under 25 atmospheres pressure, showed the complete absence of 'steam lines,' thus proving that the presence of steam is not essential to the reaction, although under ordinary conditions it undoubtedly plays an intermediary rôle. High pressure increases the direct oxidation of carbon monoxide, whilst the presence of hydrogen, as in water gas, favours the indirect oxidation. All previous explanations of the mechanism of the combustion of carbon monoxide have assumed the continuous decomposition and regeneration of steam. Prof. Bone's 'ugly' fact destroys this 'beautiful' hypothesis, and although he has no definite substitute to advance, he believes that precedent ionisation of the combining gases is the most probable explanation. A pleasing feature of an excellent lecture was the manner in which Prof. Bone gave credit to his collaborators, Messrs. F. R. Weston, R. P. Fraser, and D. M. Newitt.

AMONG the items which are to be dealt with at the forty-fifth annual meeting of the Society of Chemical Industry in London, a session of outstanding interest will be that on Tuesday, July 20, when a symposium will be held on "Corrosion." In view of the fact that this symposium is a joint meeting of the British Chemical Plant Manufacturers' Association, the Institute of Metals, the Institution of Chemical Engineers and the Chemical Engineering Group, it cannot fail to be of very general interest. British contributions will be described by a group of recognised authorities, including Mr. Ulick R. Evans, who will deal with "The Fundamental Principles of Corrosion," Mr. P. Parrish, who will speak on "Corrosion and Erosion," and Dr. W. H. Hatfield and Messrs. T. G. Elliott and G. B. Willey, who will discuss "Chemically Resistant Steels." Possibly in no branch of metallurgy has there been such great advancement, both during and since the War, as in connexion with the production of resistant steels and acid-resisting irons. Novel methods of manufacture and the alloying of some of the less common metals with iron and steel have produced alloys of a chemical resistance quite unprecedented, and the steels which are to-day being produced to withstand corrosion are far in advance of the earlier forms of stainless steels, which are chiefly martensitic. The newer corrosion-resisting steels are austenitic, *i.e.* they are softened by quenching from a high temperature, as in the case of manganese steel, whilst the acid-resisting irons have been also greatly improved recently, both from the point of view of homogeneity and toughness, resultant upon careful methods of heat treatment. Another joint meeting on the same date, of the London Section of the Society of Chemical Industry and the Biochemical Society, is on "The Scientific and Industrial Problems presented by the Hormones—the Natural Drugs of the Body," to be opened by Dr. H. H. Dale.

IN his address to the Royal Geographical Society at the anniversary meeting on June 21, Dr. D. G. Hogarth pointed out how mistaken is the impression that no important work in geographical exploration remains to be done. Apart from polar regions, southern Arabia, and central Australia, where large virgin tracts of territory exist, there still remains a great deal to do in many parts of the world in the regions intervening between known and charted routes. For intensive surveys in topography alone there is still a great field, and an even greater one for specialists in various sciences. Dr. Hogarth commented on the ever-present appetite for the sensational which tends to divert public interest and available funds from serious work to spectacular achievements. Each air dash to the Pole probably absorbs the interests, energies, and funds sufficient to furnish a dozen expeditions which would bring a hundred times more copious and valuable returns to geographical science. As a subsidiary aid to land exploration, aircraft have proved valuable; and prolonged flights are no doubt of value in the development of aerial navigation, but they can add little of importance to geographical science. The work that is required to-day is not spectacular, but it is important and varied enough to absorb all the explorers and funds available.

THAT gold exists in sea-water is a well-known fact: that it can be profitably extracted is a belief that has enabled many a company promoter to batten upon a credulous public. This belief has now received another blow. At the annual general meeting of the Verein Deutscher Chemiker, held in Kiel on May 26-30 last, Prof. F. Haber communicated the results of a research which he and Dr. J. Jaenicke have been prosecuting for several years. Whereas earlier investigators found the gold-content of sea-water to be 5-10 mgm per metric ton, their work on 5000 samples collected from many seas and from different depths has shown that the amount present is far smaller. Water from the South Atlantic contained less than 0·01 mgm. per ton, water from the bay of San Francisco a little more, and samples from the Polar seas four or five times this quantity. Melted ice from the Polar seas was often considerably richer in gold. The form in which the gold occurs in sea-water is not, as

previously supposed, as dissolved aurichloride, but as a mineral slime or as a constituent of the plankton organisms. Its separation is effected quantitatively by adding a minute amount of alkali polysulphide and a trace of copper, and then filtering through fine sand charged with sulphur. This process, however, would not be practicable on an industrial scale. Although there may be localities comparatively rich in gold, the attempt to discover them would resemble the task of hunting for a hypothetical needle in a haystack.

VISITORS to the Natural History Museum at South Kensington should find much to interest them in the greatly augmented series of enlarged models of disease-carrying insects and ticks, which has just been arranged for their benefit in the Central Hall of that institution, and of which a demonstration was given to representatives of the press on the afternoon of June 23. Initiated more than a quarter of a century ago by Sir Ray Lankester, with models of the then best known of the tsetse-flies, and of two typical mosquitos, and somewhat extended in more recent years, the series, with the latest additions, now embraces no fewer than eleven species of insects and three arachnids. The new models among the insects include representations of the internal anatomy of an infected malarial mosquito; the common household mosquito of the tropics, a carrier of the causal agent of Filariasis; the preliminary stages of the yellow fever mosquito; the tiny, midge-like transmitter of sand-fly fever, with its larva and pupa; a small West African horse-fly, which conveys the cause of Calabar swelling; the preliminary stages of one of the tsetse-fly carriers of sleeping sickness; the eggs and mouth-parts of the body-louse; and the preliminary stages and adult female of the tropical rat-flea, the most important carrier of plague. An addition to the models of ticks is a colossal representation of the transmitter of tropical African relapsing fever. Under the supervision of members of the Museum staff, the models have been executed with remarkable skill and attention to detail by Mrs. E. D. Blackman, Miss Grace Edwards, and Mr. A. J. Engel Terzi. Now that the importance of insect-borne disease to the British Empire and the world at large is receiving ever wider recognition on the part of administrators, it is well that the matter should be brought to the notice of the general public. To this end no better means than that afforded by this striking collection of models could possibly have been devised.

ENG.-VICE-ADMIRAL SIR ROBERT B. DIXON, Engineer-in-Chief of the Fleet, has accepted the presidency of the Junior Institution of Engineers for the year 1926–1927 in succession to Mr. J. S. Highfield.

MAJOR-GENERAL SIR MATTHEW H. G. FELL, K.C.B., C.M.G., has been appointed Director-General, Army Medical Services, in succession to the late Lieutenant-General Sir William B. Leishman, K.C.B., K.C.M.G.

PROF. PAUL SABATIER, For. Mem. R.S., of the University of Toulouse, and Nobel Prizeman in 1912 for chemistry, has been awarded the Albert Medal for 1926 of the Royal Society of Arts, in recognition of his distinguished work in science and of the services to industry rendered by his researches in physics and chemistry, which laid the foundation of important industrial processes.

MR. G. S. W. MARLOW has been released by the Association of British Chemical Manufacturers to devote part of his time to the appointment of secretary and editor of the Faraday Society and secretary of the Institute of Physics, pending the completion of final arrangements for carrying on the official work of these bodies. Mr. Marlow was assistant secretary to the Institute of Chemistry from 1919 until 1925.

AN earthquake of unusual violence and long duration occurred in the eastern Mediterranean at about 10 P.M. on June 26. Much damage to property was caused in Crete, and apparently, to a less extent, in Rhodes. The principal shock, as in so many of its predecessors in south-eastern Europe, was felt over a very wide area, from the Ionian Islands and Greece to Cairo and so far east as Jerusalem. The disturbed area cannot be less than 1200 miles long from north-west to south-west, and about 800 miles wide, the total area being about 750,000 square miles. The epicentre was probably near Crete and between that island and Rhodes.

IN view of the enormous amount of scientific and other special information now available in periodicals and libraries, an association—The Association of Special Libraries and Information Bureaux—was formed to assist in making such information available to all who wish to use it. With the assistance of the Carnegie United Kingdom Trust the Association has undertaken, as one of its first activities, the compilation of a directory of sources of specialised information in Great Britain and Ireland. The general editorship of this work has been entrusted to Mr. G. F. Barwick, formerly Keeper of Printed Books at the British Museum.

PROGRESS is being made towards uniformity in the issue of wireless time signals. We learn that the signal from the Cape is now to be brought into line with the modified Onogo system recommended at the meeting of the International Time Commission in July 1925 and issued from the French stations since the beginning of this year. This signal is emitted from the Slangkop Wireless Station and originates at the Royal Observatory, Cape of Good Hope. The change requires the introduction of a new transmitting apparatus, the cost of which is to be defrayed by the Union Government. Multiplicity in the form of time signals is nothing but a disadvantage, and the change will be a great satisfaction to users of the signal and especially to mariners. It is expected to come into operation early in 1927.

THE Royal Sanitary Institute is celebrating its jubilee by holding an Imperial Congress at the Central Hall, Westminster, on July 5-10, under the presidency of the Minister of Health, the Right Hon. Neville Chamberlain. More than 1000 delegates have been appointed to attend by Government Departments,

including and Northern Ireland, the Ministry of Agriculture, H.M. Office of Works, the Home Office, War Office, Board of Control, and the Air Ministry. Many foreign governments, and municipal authorities, learned societies, and universities throughout the United Kingdom will also be represented. In connexion with the celebrations a handbook has been prepared recording the history and activities of the Institute, together with special articles dealing with sanitary progress during the fifty years 1876–1926, from the medical, engineering, architectural, parliamentary, legal, public administration, colonial, military, and naval aspects.

The American Chemical Society, which was founded in 1876, celebrates its fiftieth anniversary in Philadelphia, Pennsylvania, U.S.A., on September 6-11 next. It is anticipated that some 3500 chemists from all parts of the world will be present. The Society will meet in eighteen divisional gatherings, dealing with various branches of pure and applied chemistry. Many of the divisions will hold special symposia of papers and addresses of importance from authorities in their respective fields. In addition, there will be two general meetings of the whole Society. No direct invitations or requests for the appointment of special delegates are being sent out; all non-American chemists are invited to attend and take part in the meeting on the same basis and under the same conditions as members of the Society. Foreign chemists expecting to attend the meeting should, if possible, communicate with Charles L. Parsons, Secretary, Mills Building, Washington, D.C., U.S.A.

The latest catalogue of Messrs. Heffer and Sons, Ltd., Cambridge, (No. 269) is devoted to second-hand books on physiology, anatomy, medicine, zoology, biology, anthropology, and ethnology. Many of the works listed are from the libraries of the late Sir William Bayliss and Sir Francis Darwin. The publishers offer the catalogue free upon application.

Messrs. Watts and Co. are about to reissue, in two volumes, Herbert Spencer's "Autobiography," which for some time has been out-of-print. They have also begun a new cheap series of volumes entitled "The Forum." Among future works will be "The Origin of Life," by Sir Edward Sharpey Schafer, and "The Goodness of Gods," by Dr. E. A. Westermarck.

Messrs. Bernard Quaritch, Ltd., 11 Grafton Street, W.1, have just issued another useful catalogue—No. 400—dealing with some 2000 second-hand works on botany, agriculture, early medicine and surgery, forestry, fruit-culture, gardens and gardening, herbals, modern medicine, and tobacco. It should certainly be seen by all readers interested in these branches of knowledge.

Our Astronomical Column.

The Atmosphere of Mars.—In August 1924 Mr. Wright obtained at the Lick Observatory photographs of Mars in ultra-violet, yellow and red light. The former showed a larger image than the others, but gave scarcely any detail on the planet's surface. B. Fessenkoff, of the Moscow Astrophysical Institution, makes some calculations on the subject in *Astr. Nachr.* No. 5450. He concludes that the observed facts are best satisfied by supposing that the upper layers of the planet's atmosphere contain fine dust which is nearly opaque to ultra-violet light, but transparent to red and yellow light. As to the possibility of fine dust at great heights, reference may be made to the Krakatao eruption of 1883. The dust remained suspended in the upper air for more than a year, causing remarkable sunsets all over the world.

The Polar Compression of Uranus.—An article by C. Wirtz in *Astr. Nach.* No. 5441 gives a new estimate of the oblateness of Uranus by comparison of its brightness at the Uranian equinoxes and solstices. The inclination of the axis is so high that at the solstices, which occurred in 1861 and 1903, the terminator practically coincides with the planet's equator, and the outline appears almost circular; at the equinoxes, which occurred in 1882 and 1924, the poles are on the terminator, the oblateness reaches its maximum and the light a minimum. A discussion of all the available determinations gives the magnitudes as $5{\cdot}46^m$ at maximum, $5{\cdot}67^m$ at minimum. The light-range is concluded to be between $0{\cdot}15^m$ and $0{\cdot}25^m$, from which a compression in the neighbourhood of $\frac{1}{14}$ is deduced. The author concludes that long-continued photometric measures by modern methods would determine the compression more accurately than micrometrical measures of the disc. The range in the values found by the latter method is considerable.

Cepheid Variability.—In an article on the δ-Cephei problem, published in the *Atti della Pontificia Accademia delle Scienze (Nuovi Lincei)*, the Rev. J. G. Hagen, S.J., Director of the Vatican Observatory, deprecates the antagonism which has arisen between the two theories which have been advanced to explain the variability of the light emitted by stars of this type. In some papers, especially those in English, the pulsation theory is referred to as the generally accepted theory, while, in a recent publication of the Ottawa Observatory, it is asserted that the ordinary binary theory may almost certainly be definitely ruled out of court. Such statements are scarcely justified in view of the fact that no clear and precise answer has yet been given to the questions: (1) Where does the impulse for the pulsations come from? And, (2) how are the pulsations maintained uniform for centuries? A natural answer is furnished to both of these queries if a δ-Cephei star is regarded as a binary system; the pulsations would then be periodically excited by the approach of the satellite and would last only from one eruption or light maximum to the next. In this way the mathematical theory of pulsations receives the mechanical basis hitherto lacking, and, moreover, the undulations observed in the descending branches of the light curves find their most obvious explanation. On the other hand, no invincible argument against the presence of a satellite has ever been brought forward. So far as analogy with other celestial phenomena is concerned, there is in the entire heavens no well-proven example of periodic changes due solely to the internal forces of a star, especially now that some long-period variables have revealed themselves as binary systems, whilst striking examples of light eruption are provided by comets approaching the sun.

Research Items.

THE PERUVIAN QUIPUS.—Baron Nordenskiöld continues his study of the quipus, the systematically knotted cords found in Peruvian graves, in the second part of No. 6 of his "Comparative Ethnographical Studies" (Göteborg: Elanders Boktryckeri Aktiebolag). He here follows up his previous suggestion that the quipus have a calendrical significance by a detailed study of seven quipus on a numerical evaluation of the knots according to their position and the colour of the cords. As regards the ancient Peruvian calendar, the statements of early writers are ambiguous and contradictory as to the division of the year into months, the extent to which the distinction between the lunar and solar year was recognised, and the date on which the year began. It is possible that this confusion arose out of the fact that the more intimate and accurate knowledge of the calendar was confined to the priests, with whom the whites were less likely to come into contact, while the common people, from whom these writers obtained their information, used the lunar year; the solar year, divided up into months of thirty days with five intercalary days, being the property of the learned and not in general use everywhere. Certain results common to the quipus here examined are found to emerge from the numerical evaluation. It would appear that the Incas worked with solar years of 365 days and with months of either 29½ or 30 days, the classification of knots according to the colour of the strings producing both results on the same quipus. The number 7 has special significance. The Incas worked both with synodical months and with a division of the year into 12 months of 30 days plus 5 extra days. It is possible that they knew and reckoned with a synodical revolution of Jupiter calculated at 397 days. The results obtained support the statements of the old writers.

STONE IMPLEMENTS FROM NORTH-WEST PERU.—Relics of a remarkable lithic industry found in north-west Peru are figured and described by Mr. C. Barrington Brown in *Man* for June. Flakes apparently made by human agency were first observed in 1911 at Punta Picos, south-west of Tumbez, on the sandy surface of an ancient sea floor now sixty feet above sea-level. They were of the simplest type and of various materials, showing in every case one side as a single fracture. Later similar flakes, with a few showing secondary pressure flaking along an edge, were found at many different sites, on hilltops and slopes, river terraces and plains. In 1924, on the occasion of a second visit to that locality, not only large quantities of flakes, several reworked, were found, but also stone implements of a skilled manufacture, polished axes, mortars, bowls, etc. At the head of a canyon was found a piece of worked slate which may be a phallus. In three places flakes were found with modern Inca remains which may have been due to Inca occupation of ancient sites. So far, finished implements have been found in one locality only. In the majority of cases no pottery fragments, no bones, and no metal were found. The most interesting and important site is that of El Estero, a small pond 22 miles inland due east from Cabo Blanco on the highest point, at an elevation of 85 feet above sea-level, of a low pass through the Buitre hills. Most of the axe-heads and implements were lying on the surface a few yards from the trail. The area of habitation covers about 1000 square yards with an accumulated thickness of reddish-grey earth of about 4 feet. Here thirty-one axe-heads were found, all except one showing a feature unique in axe-heads, the sides and butt being filed down into a flat or slightly concave face. The butts are provided with protuberant ears of unusual shape. Two examples from Ecuador in the British Museum have the protuberant ears but not the typical flattened butt and sides. The absence of pottery suggests a pre-Inca industry.

BIRDS IN SOUTH AMERICA.—Comparatively little is known of the migration of birds in the southern hemisphere, and in order to some extent to repair this blank, A. Wetmore spent ten months in the southern States of South America, particularly to observe North American birds in their winter quarters, and of these more especially the waders. The results of this expedition, which lasted from June 1920 until April 1921, have recently been published (Smithsonian Institution, *United States National Museum Bulletin*, 133, "Observations on the Birds of Argentina, Paraguay, Uruguay, and Chile"). They comprise much more than the main object of the journey, for his travels in Argentina, Paraquay, Uruguay, and Chile brought the author in contact with many native birds, regarding which he has made comprehensive and excellent field notes. The descriptions of several racial forms new to science have already appeared in other scientific publications, but are here repeated. Many valuable notes on migration, a detailed itinerary, a good map, and many excellent photographs of the various types of bird country, add to the interest of this contribution to the knowledge of South American bird life.

THE SOURCE OF HYDROGEN SULPHIDE IN THE BLACK SEA WATERS.—It has long been known that the upper layers of the waters of the Black Sea only are free from hydrogen sulphide, which is present from the depth of 150 metres downwards, so that no life except bacteria is possible between 150 metres and the bottom (2188 m. in the deepest parts). Nothing was known, however, as to the origin of this hydrogen sulphide, and only recently Prof. B. L. Issatchenko has proved that it is produced from the sulphates dissolved in water by anaerobic bacteria similar to *Microspira æstuans*, known from the northern seas. The Black Sea organism is exceedingly active and can produce so much as 0·3 gm. of hydrogen sulphide per litre of water. Apart from this organism, there are in the bottom mud of the Black Sea some other bacteria able to produce hydrogen sulphide from albumins, but their productivity is far lower and the conditions for it in the depth of the sea are less favourable. Another problem investigated by Prof. Issatchenko was why the surface layers of water are free from hydrogen sulphide. This was formerly ascribed to the presence of an intermediate layer populated by bacteria which are able to oxidise hydrogen sulphide produced in the deeper waters. No such bacteria could be found by a systematic sampling of water, and it is concluded that the oxidation of hydrogen sulphide in the upper layers is due simply to the circulation of water (*Priroda*, 1925, Nos. 4-6).

DUSTING BY AEROPLANE AGAINST MOSQUITOES.—Circular 367 of the United States Department of Agriculture is devoted to an account of experiments carried out for testing the possibilities of employing aeroplanes in the control of the breeding of Anopheles mosquitoes. The authors, Messrs. W. V. King and G. H. Bradley, mention that Paris green was distributed from aeroplanes on the extensive marshes and swamps near Mound, Louisiana, in 1923 and

1924. As the Paris green is effective in very small quantities, it was diluted by mixing with an inert carrier, fine silicious earth being mostly used. No special difficulty was experienced in distributing the insecticide over open water or rice fields: the most difficult conditions encountered were in heavily wooded areas where the water was protected by dense foliage. In the latter conditions a larger amount of the arsenical is required as compared with about half a pound per acre in open areas. The two final tests of 1924 gave particularly clear-cut results. In areas overgrown with aquatic vegetation, 88 per cent. to nearly 100 per cent. of the Anopheles larvæ were destroyed. Controls were made by the use of open porcelain pans of water containing ten larvæ each. These were placed at the different stations before the dust was applied by aeroplane, and were examined the following day for the percentage of larvæ killed.

GENETICS OF THE CABBAGE TRIBE.—The cabbage tribe forms an interesting variation group. All the forms of cabbage, kale, kohl rabi, brussels sprouts, broccoli and cauliflower, are believed to have been derived from the wild *Brassica oleracea* found on various European coasts, for example, on the cliffs at Dover. The ancient Greeks recognised three varieties. The others have appeared since, but little is known as to how or when. Mr. M. S. Pease (*Journ. Genetics*, vol. 16, No. 3) is making a genetical study from crosses of savoy, kale, and kohl rabi. Kale is found to have two independent factors, in the absence of which the cabbage heart develops, one factor giving an intermediate condition. Malinowski found three polymeric factors for heart in certain other cabbages. The heart factor also shows linkage with a number of others, and some of these linkages, as of curly leaf with heart, are of peculiar character, showing a strict association between degrees of hearting and degrees of smoothness. Although there is difficulty in classifying degrees of hearting, Pease obtained consistent results by growing the F_3 and F_4 and back-crossing. A peculiar monstrosity (*Asparagodes*) in which leafy outgrowths occur on the midribs of the leaves, was first described in Gerarde's "Herbal," but is believed to be as old as the Greeks. It behaves as a simple dominant in crosses. Another independent factor gives the difference between the purple and green types. Pease distinguishes in addition two linkage groups, one containing a factor (*a*) for heart, (*b*) for tallness, and (*c*) for curliness of leaves. The other group contains the other hearting factor as well as factors for petioles, lyrate leaves, and broad leaves. Thus four linkage groups have already been recognised, while the number of chromosome pairs is nine. Difficulties of observation arise from the fact that the multiple factors frequently give an apparently continuous series of variations, and self-sterility is also involved.

UNUSUAL FORMS OF FOSSIL CRINOIDS.—Among the unusual forms of crinoids described by F. Springer (*Proc. U.S. National Museum*, vol. 67, art. 9, 1926) are those in which the stem loses its characteristic shape, becomes coiled, and the columnals (stem plates) are flattened or concave at the inner side and consequently crescentic or elliptical in cross-section; the cirri, instead of occurring in whorls around the stem, are borne only in two rows at the flattened or concave side. In such crinoids there is a tendency for the crown to bend back upon the stem, and for the stem to coil around it in the opposite direction in such a way that the crown may be tightly enclosed within the coil and completely enveloped by the cirri. This character, which was evidently protective, originated independently in a number of unrelated genera ranging from the Silurian to the Carboniferous. Other crinoids are described with the arms in a recumbent position instead of being outstretched or folded together as is the case with existing forms; in these the arms were normally pendent, with the dorsal side pressing backward upon the calyx and stem.

THE DEPTH OF ORIGIN OF EARTHQUAKES.—More than any other living man Mr. R. D. Oldham has helped to bring the science of seismology to its present vigorous state, and his latest contribution to the subject is, like most of his work, of fundamental importance. Dealing with *episeisms* (surface shocks) as opposed to *bathyseisms* (deep-seated shocks), Mr. Oldham shows that the depth of origin can be calculated from an empirical formula based on the intensities at a point directly above the disturbance and at another distant point (*Q.J. Geol. Soc.*, vol. 82, 1926, p. 67; and *The Observatory*, March 1926, p. 86). Loss of energy by absorption is allowed for from a study of earthquakes that have been worked out in great detail. Applying the formula to 5605 Italian shocks that occurred between the years 1897 and 1910, he finds that 90 per cent. originated at depths of less than 8 km.; and only 1 per cent. gave a depth greater than 30 km. From the long-distance records of bathyseisms, Prof. Turner has found that most of these disturbances originate at a depth of about 200 km., with smaller proportions at about 100 km. and 500 km. Fracturing of the rocks of the outer crust is by far the most probable cause of the surface shocks, but this explanation is out of the question for bathyseisms. Changes of state accompanied by changes of bulk might cause the long-distance earthquakes and at the same time fracture the surface rocks, thus leading to a nearly simultaneous episeism. The San Francisco earthquake was a compound phenomenon of this kind. The local effects indicated a depth of 20 km., while the long-distance records gave 140 km. Seismology thus becomes the study of two very different types of earthquakes.

GEOLOGICAL TIME.—In the *Phil. Mag.* for May 1926, pp. 1055-74, Dr. Arthur Holmes gives a review of all the evidence in favour of the longer estimates of geological time which have been based on lead-ratios. The adverse criticisms by Prof. Joly are shown to be founded either on faulty data, or on speculations that are not necessarily true. The sodium method is rejected on grounds already reviewed in NATURE (April 24, p. 592). It is suggested that the discrepancies in thorium minerals are due to the fact that lead present as oxide or silicate would be more easily removed by percolating waters than the lead in uranium minerals, which is most probably present as a highly insoluble uranate. An analysis of atomic weight determinations on lead from thorium minerals supports this conclusion, and shows further that there can be very little actinium D in 'uranium lead.' Thus the ages calculated from the lead-ratios of uranium minerals, if they are otherwise free from suspicion, cannot be more than a few per cent. too high. The variation in the radii of uranium haloes is shown to be explicable by other hypotheses besides that advocated by Joly, so that no evidence is valid along this line of attack until the istopic constitution of 'uranium' has been revealed. It is concluded that the time elapsed since the crystallisation of the middle pre-Cambrian pegmatite-minerals of Norway, Sweden, Texas, Ontario and Africa is of the order of 1000 million years. No higher ages are yet well established, though the age of the oldest rocks must, of course, be considerably greater than these of the middle pre-Cambrian.

Rate of Aeration of Water.—W. E. Adeney has published a series of observations in which he has determined the rates of solution of oxygen, expressed in percentages of saturation, by films of de-aerated fresh, or salt waters, 0·05 cm. thick, when uniformly exposed to the air, and independent of evaporation and downward streaming ("On the Rate and Mechanism of the Aeration of Water under Open-air Conditions," *Sci. Proc. Roy. Dublin Soc.*, 18 (No. 20), 211-217, April 1926). This has been followed by determinations of the rate of solution by quiescent columns of water. Owing to the cooling produced by evaporation, minute streamlets sink towards the bottom. In the case of salt water, density changes also assist the mixing. Movements occurring at the surface facilitate the saturation of the water with gas. Quantitative results are given for certain limiting cases, and suggestions made as to the probable values under various intermediate conditions.

Spectra of Exploded Metals.—In the *Scientific Papers of the Institute of Physical and Chemical Research*, Tokyo, vol. 4, No. 48, T. Hori describes some interesting experiments on the spectra of exploded metals by the method of Anderson. A thread of mercury contained in a fine capillary tube, when exploded in that way, gave a good continuous spectrum crossed by some absorption lines of mercury. Other metals gave a less satisfactory continuous background, but when exploded in the form of fine tubes containing mercury, many absorption lines were seen on the continuous spectrum produced by the mercury. Under reduced pressure the Swan spectrum appeared in absorption by this process, owing to the presence of oil in the explosion chamber. A satisfactory substitute for mercury as the source of the continuous background was found in incandescent carbon particles produced by placing asbestos fibre saturated with petroleum at the exploding centre. Several absorption spectra—including bands of compounds and series and non-series lines of elements—were produced by this device. In the same volume (No. 56) Messrs. Fukuda, Kuyama and Uchida record the appearance of several lines, forbidden by the spectroscopic selection rules, in the spectra of constricted arcs *in vacuo*, while Fukuda, in No. 55, records the production of similar lines in vacuum tubes carrying heavy discharges.

Carbon Tetrafluoride.—In the issue dated May 31 of the *C. R. Acad. Sci.*, Paris, Messrs. P. Lebeau and A. Damiens give an account of the preparation and properties of carbon tetrafluoride, CF_4, from which it would appear that the compounds previously described under that name were far from pure. By the direct action of fluorine on various forms of carbon and passing the products of the reaction through a vessel cooled with liquid air, a colourless liquid is obtained which, from its varying boiling-point, is obviously a mixture. The most abundant constituent of this mixture was isolated by repeated fractional distillation and was found to boil at about $-150°$ C. The gas is odourless and without action on water, is not attacked by aqueous or by alcoholic potash (differing from the gas hitherto described as carbon tetrafluoride by Moissan and by Chabrié), and is not even attacked by fused potash at 740° C. Its composition was established by the reaction with sodium heated to 500° C., which is according to the equation $CF_4 + 4Na = C + 4NaF$. It also reacts with metallic calcium at about 700° C., giving calcium fluoride, calcium carbide, and carbon. A repetition of the work of Chabrié has established that the substance described by him as carbon tetrafluoride was a mixture, the principal constituent of which was a fluochloride, CCl_2F_2.

Propagation of Radio Waves.—Radio engineers are making strenuous endeavours to understand the mechanism of radio transmission. The Radio Corporation of America and its associated companies are making systematic researches, both theoretical and experimental, to discover this mechanism. They admit that electric currents in wires, in a vacuum and in electrolytes, can be explained by means of the electron, but the structure of the electromagnetic field still remains a mystery. Each new discovery in long-wave and short-wave propagation is eagerly studied with this end in view. This is shown in the paper read by E. F. W. Alexanderson on radio wave propagation to the Academy of Swedish Engineers in July of last year. After describing the various phenomena generally referred to as 'fading,' he divides the waves sent out from a radio station into the earth-bound wave, which is guided by the proximity of the conducting earth, and the space wave or high angle radiation, which is guided by refraction in an ionised layer in the upper atmosphere. Long-wave telegraphy depends mainly upon the earth wave. Short-wave long distance communication depends entirely upon the space wave. Broadcast reception depends upon the earth-bound wave for near stations, and on the space wave for distant stations. It is stated that at a distance of about 100 miles from the station the intensities of the two waves are nearly equal. It has been found that at a distance of ten miles from a fifty-metre station the plane of polarisation of the space wave has been twisted by between 20° and 30°. It follows that at some distance between 60 and 90 miles the twist would be 180°. The earth-bound wave maintains its vertical plane of polarisation; the two waves, therefore, may cancel one another at a distance of about 100 miles. This explains 'blind' spots. As a model of radio transmission, he discusses the motion of a horizontal rubber sheet actuated by a vertical shaft making rotatory oscillations. Straight lines drawn on the rubber sheet will appear to have a wave motion. In order to reconcile the old and new points of view he thinks it necessary to prove that the electron is an entity with an aurora reaching from it into infinite space.

A New Reflex Camera.—Reflex cameras possess many advantages, particularly in regard to instantaneous photography, over those of the ordinary type. The 'Press' reflex camera recently placed on the market by Messrs. J. H. Dallmeyer, Ltd., 31 Mortimer Street, London, W.1, should help, in large measure, to meet the demand for an instrument of this type at a reasonable price. We have examined one of these cameras, and find it a serviceable and well-made instrument, easy to manipulate, and capable of giving excellent results. It is fitted with a single wind, self-capping, focal-plane shutter, giving speeds from $\frac{1}{15}$th to $\frac{1}{1000}$th of a second and capable of adjustment for time exposures. The shutter runs very close to the plate, and is smooth and easy in action. The hood is detachable and can be fixed at right angles to its normal position. The reversing back is fitted with a hooded focussing screen, which can be used when the camera is mounted on a stand and critical focussing is required. Sufficient extension is provided to enable objects at a distance of about 18 in. to be brought into focus. The camera can thus be employed for photographic work in the laboratory. The outstanding feature of the equipment is the Dallmeyer 6 in. focus, f/3·5, anastigmatic lens, which gives excellent definition over the whole field. Its large aperture makes it extremely useful for very short exposures, as in certain types of Nature photographs, or for indoor and other work under restricted lighting conditions.

Explosions in Gaseous Media.

A GENERAL discussion on different aspects of explosions in gaseous mixtures took place at a meeting of the Faraday Society held on June 14 at the Institution of Mechanical Engineers, Westminster. The afternoon session, presided over by Prof. H. B. Dixon, was devoted to the consideration of explosions viewed quite generally. In an introductory survey of the subject, Dr. Garner pointed out the large number of factors which have to be considered. The rate of travel of a flame in a gaseous mixture appears to be intimately connected with the amount of preheating—probably by radiation from the flame-front—and with the thermal conductivity of the mixture. It is probable that catalysis also plays an important part in the spread of flame, and a number of substances were mentioned which can be regarded as positive and negative catalysts respectively. Dr. Garner described a possible mechanism which he termed energo-thermal catalysis.

The ignition temperatures of gas mixtures are very important both from the academic and the practical points of view; Prof. Dixon described recent results which he in conjunction with Messrs. Harwood and Higgins had obtained. Using the concentric-tube method, the temperature to which the furnace must be heated before ignition of the gas mixture takes place is dependent upon the time the hot gases are allowed to remain in contact; the true ignition temperature is taken as being that at which the gases unite immediately after mixing. There appears to be a crucial pressure for each gas at which the ignition point is highest; above and below this pressure the ignition point falls. Using the method of adiabatic compression, comparisons were made between the results obtained with two different pieces of apparatus in which the rates of compression were not identical; the lag between the completion of the piston stroke and the recoil due to explosion is shortest when the compressions are highest.

Methods of measurement of the radiation emitted during explosions in closed vessels were described by Prof. David. The infra-red radiation in coal-gas air explosions is at a maximum during the explosion period and before the mean gas temperature attains its maximum value; it is assumed that the radiation is therefore mainly due to chemical activity and not simply to temperature. The introduction of infra-red radiation can speed up the combination in a closed vessel provided that (1) the radiation is of the kind which is absorbed by the combustible gas; (2) nitrogen is present as a constituent of the inflammable mixture; and (3) the mixture composition is such as to be favourable to the formation of oxides of nitrogen during combustion. In the discussion, Mr. Finlayson suggested that the shape of the explosion vessel might have an important effect upon the results obtained, and Dr. Ellis showed some interesting photographs of the mode of flame propagation in closed vessels of different shapes.

The subject of ionisation in gas explosions was introduced by Dr. Garner and Dr. Saunders. It was pointed out that the results obtained by different investigators are not in entire agreement, but the following tentative conclusions can be drawn: (1) The ionisation occurring in gas explosions is mainly thermal, although certain experiments seem to indicate that a small fraction is due to chemical change. (2) Ionisation plays no part in the ignition of gases. (3) It appears unlikely that the ionisation of the gas in front of the explosion is the cause of the propagation of the detonation wave. (4) The action of anti-knocks and knock inducers in the petrol engine cannot be explained on the theory that these substances change the ionisation in the explosion wave. Similar views were expressed in a communication from Dr. Lind.

The importance and the applicability of rates of flame propagation were discussed by Dr. Payman in presenting the results of experiments by Prof. Wheeler and himself. The conditions of flame propagation under which the 'law of speeds' has been found to hold were considered, and it was pointed out that from this law it is possible to calculate the speed of uniform movement in any mixture with air of an industrial gas, the speed of uniform movement of the individual gases with air being known. In the discussion on this paper the point was raised whether the speed of uniform movement could truly be regarded as a physical constant. A short account of recent experiments in Prof. Bone's laboratory was given by Dr. Fraser, and photographs were exhibited showing the movement of the flame in carbon-monoxide-oxygen mixtures. Prof. Jorissen contributed to the discussion some remarks on the limits of inflammability of gases.

The rates of detonation of cyanogen-oxygen mixtures were dealt with in a paper by Dr. Campbell and Prof. Dixon. The detonation velocities in the rapid mixtures appear to be almost independent of the diameter of the containing tube. This is not the case with mixtures largely diluted with nitrogen; in the most highly diluted, the detonation wave is probably never established. From the velocities in the rapid mixtures the mean specific heats of mixtures of carbon monoxide and nitrogen at high temperatures have been calculated.

At the evening session, under the chairmanship of Sir Dugald Clerk, explosive reactions were considered in reference to internal combustion engines. In a brief introduction Sir Dugald Clerk reviewed the work on this branch of the subject carried out by himself and others during the last fifty years. Prof. David discussed the extent to which incomplete combustion of the charge is responsible for limiting the pressures developed in gas engines; about 10 per cent. of coal-gas remains unburnt at the moment of maximum pressure. Various factors which may affect the rate of combustion in gas engines were touched upon. The greater the degree of turbulence of the gaseous charge the more rapidly will inflammation spread; the temperature of the gas engine charge appears to have only a slight effect on the rate of inflammation, but it seems possible that the radiation from the cylinder walls may exert an appreciable influence.

From his experiments with petrol engines Mr. Tizard advanced the view that the dissociation of carbon dioxide at the temperatures reached is sufficient to account for the important fact that maximum power first occurs with slightly 'rich' mixtures and remains practically constant over a considerable range in strength of mixture. In regard to the possibility of detonation of a 'pure' fuel, this appears to depend upon whether a certain temperature, characteristic of the substance, can be exceeded. Anything which lowers the maximum temperature reached during the explosion will tend to stop detonation. The view was put forward by Messrs. Sims and Mardles that metallic anti-knock compounds suffer thermal decomposition, and that the colloidal metal so produced brings about a decrease in volume of the unburnt charge ahead of the flame. Easily oxidisable metals like lead, nickel and iron give positive results as anti-knock compounds, whilst silver and gold are not effectual. Prof. Dixon, Prof. Marks, Messrs. Finlayson, Kay, Sutton, Whatmough and others, contributed to the discussion.

C. C.

The Eastman Universal Colorimeter.

THE Eastman Kodak Company, of Rochester, N.Y., U.S.A., has placed on the market a very useful colorimeter (Fig. 1) which has a greater range of utility than many other instruments of this kind. Originally designed by L. A. Jones (*Journal of Optical Soc. America*, 4, 420, 1920) for use in connexion with war-time problems of visibility and the measurement of the colours of sea and sky, it has been adapted, by the addition of various accessories, for the majority of laboratory and industrial requirements.

The fundamental basis of its action is the phenomenon of the so-called "subtractive colour mixture."

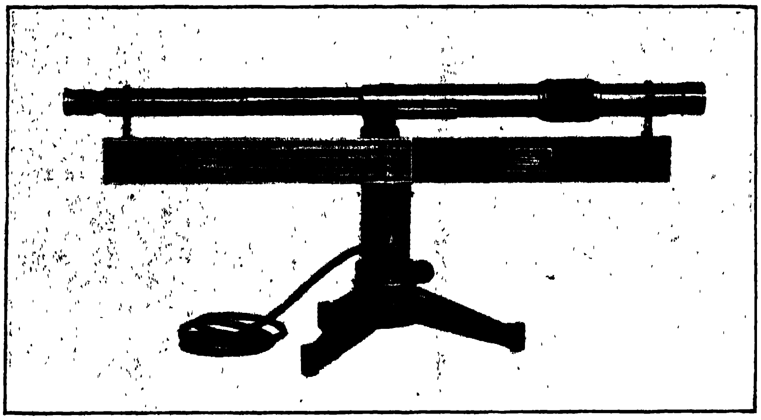

FIG. 1.—The Eastman colorimeter.

To illustrate this we may imagine three colour filters for which, in turn, the main absorption is in the red, green, and blue parts of the spectrum; thus the filters will appear blue-green, magenta, and yellow, respectively. It will easily be understood that by using these in pairs, the primary colours red, green, and blue may be produced in the transmitted light.

For the purposes of the colorimeter these subtractive primaries (blue-green, magenta, and yellow colour filters) are used in the form of long and thin wedges of dyed gelatine, suitably mounted so that various thicknesses of the absorbing medium can be introduced into the light beam by sliding the wedge parallel to its own length. By this means it is possible, for example, to 'mix' varying amounts of yellow with blue-green in order to obtain a series of greens varying from blue green to yellow green, and so on; the use of all three wedges in considerable thicknesses will produce the darker colours. A neutral wedge and supplementary colour filters are added to increase the colour range, which includes all hues and saturations up to high values. Only some of the most highly saturated colours cannot be matched, such as, for example, a very strong emerald green.

The colorimeter is so built that light derived from a standard electric lamp and passing through the wedges illuminates one half of the field of view, while the other half is illuminated by light from the object under test. Thus the colours of objects may be measured *in situ*, or samples may be specially mounted and illuminated for examination in the fittings which are provided; these include one designed for opaque objects, another for colour filters, and another which is designed to intensify the hue component in colours of low saturation by the use of multiple reflections from the coloured surface.

The colour scale is necessarily arbitrary, but it is claimed that an adequate permanency of the wedges has been secured, so that the instrument as it stands should be of utility for such industrial purposes as the standardisation of paints in manufacture and the like, but it is not easy to judge how far the scales of separate instruments of this kind would agree.

In order to convert the readings of the instrument into the usual colorimetric terms of 'hue, saturation, and brightness,' a special calibration of the wedges would be necessary; the accurate transformation would always be a somewhat cumbersome process, though time could be saved by suitable tables and graphical methods.

The instrument is well made and finished, and is very simple in operation. Provided that the difficulty of dealing with highly saturated colours is borne in mind, it should meet the needs of many who have to make colorimetric measurements. L. C. M.

The World's Forestry Congress.

THE World's Forestry Congress was held at Rome on April 29-May 5. The meeting was preceded by a visit on April 27 to the Milan Exhibition, at which a certain number of delegates inspected the forestry exhibit and a section dealing with wood-utilising machinery. Fifty-eight countries were represented at the Congress, most having from two to five Government delegates and a varying number of others who represented their countries but were not specially deputed to do so. Most of the European countries had strong deputations, as also had the United States of America. The heads of the delegations representing Great Britain and the Government of India respectively were Lord Lovat and Prof. E. P. Stebbing.

At a preliminary meeting of the Technical and Scientific Committee on April 28, the honorary presidents, president, and vice-president of the Congress were elected, and afterwards the presidents and vice-presidents of the five sections into which the Congress was divided for working purposes. The presidents of the Congress were Italians. The vice-presidents were from Germany, United States, Great Britain, Dutch East Indies, Japan, and Norway, and the presidents of sections from Sweden, Czechoslovakia, Spain, France, and Brazil.

The opening meeting of the Congress was held on April 29, H.M. the King of Italy and M. Mussolini being present. This was followed by a general meeting, and later by a meeting of heads of delegations at which the work to be carried out was finally sanctioned. Two days, May 31 and June 1, were devoted to a visit to the Forest School at Florence, and to an excursion to the forest of Vallombrosa. Three days were allowed for the work of the sections, each section having three meetings of three hours each. Sections I. and III. met at the same hours, and sections II., IV. A and IV. B. It was not therefore possible for any one delegate to attend all the meetings of each section. Since many Governments were well

represented this would have been immaterial had the agenda of each section been confined to well-defined branches of forestry. Unfortunately, however, there was a certain amount of overlapping, and this proved somewhat of a hardship. Some transfers of subjects were made between sections, at the request of presidents and vice-presidents. It became inevitable, but proved rather confusing for the rank and file of the delegations.

Briefly, Section I. confined itself to questions dealing with forestry statistics, policy, economics, legislation and instruction in sylviculture; Section II., trade and industry in timber, and in forest products in general; Section III., technical problems relating to sylviculture and forest management; Section IV, A, control of torrents, reafforestation of mountain areas, plant diseases and wind damage, forestry propaganda and improvement of game and fisheries; Section IV, B, tropical forestry resources, sylviculture, protection and management and research in tropical forests, uses and export of tropical timbers. Resolutions on these matters were passed by each section and were accepted at the final general meeting of the Congress on May 5.

Linguistic difficulties were of course a great trouble, and resulted in an enormous waste of time. The languages declared for use were French, English, German, Italian and Spanish. The last two were given up at the outset. French was the language used from the chair at all meetings, and was the language (with English) used in the daily reports of agenda, etc., issued during the meeting. But translations into English or German had constantly to be made during the meetings. It is obvious that a certain responsibility rests on Governments in this matter, and that however eminent a man may be in his own branch of study, he loses the greater part of his utility to his Government, and wastes the time of an International Congress, if he can only speak his own language.

Some 247 papers were presented to the Congress, a proportion only being read in précis form. That the Rome Congress was a success is beyond doubt. A careful study of the proceedings will show that work of a very valuable character was accomplished, which should prove of use to the Governments of the various countries which have forest areas of importance to conserve.

University and Educational Intelligence.

CAMBRIDGE.—Mrs. Pilcher, sister of the late Prof Lewis, has offered her brother's house, 2 Fitzwilliam Road, to the University in accordance with his wishes. The rent is to be devoted to the Mineralogical Museum, particularly to the purchase of specimens and books.

Mr. A. J. Dorward, Trinity College, has been appointed University lecturer in moral science. Dr. Cobbett, Trinity College, has been re-appointed University lecturer in pathology. Mr. A. Hutchinson, Pembroke College, has been elected professor of mineralogy in succession to Prof. Lewis, who died on April 16 last.

The Council of Trinity College is inviting applications from Bachelors of Arts, or those admitted to the title of a degree, for a Rouse Ball travelling studentship in mathematics, the purpose of which is to enable the student to study mathematics or the application of mathematics in a foreign university or school.

The Master and Fellows of Pembroke College announce that they will shortly make an election to a Stokes Studentship for research in physics or subjects cognate thereto. The value of the studentship is between 400*l.* and 450*l.* a year, and the tenure will be for three years with the possibility of renewal for a further period not exceeding five years. Candidates may be of either sex and must be between 23 and 30 years of age. They must have shown capacity for research in mathematical or experimental physics or in subjects cognate thereto, such as physical chemistry or the study of physical laws in relation to living matter. Preference will be given to graduates of the University of Cambridge.

The Henry P. Davison scholarships have been awarded to F. P. R. Howard, Trinity College, A. Macdonald, St. John's College, and C. D. G. Nicholson, Jesus College. The scholars will proceed to Harvard, Yale, and Princeton Universities respectively.

GLASGOW.—At the graduation ceremony on Wednesday, June 23, busts of the late Sir William Macewen were presented to the University and to Lady Macewen.

The following were presented for the degree of Doctor of Science (D.Sc.): Mr. R. V. Hansford, for a thesis entitled "A Description of a High Frequency Generator utilising Thermionic Valves and forming part of a Modern High-Power Radio-Transmitting Station," with additional papers; Mr. J. P. M'Hutchison, for a thesis entitled "Researches in Radioactivity with the Radio-Elements Radium D and Radium E."

LONDON.—Mr. Justice Tomlin (chairman), Sir Amherst Selby-Bigge, Sir Cyril Cobb, Sir Josiah Stamp, Sir Cooper Perry, Mr. A. D. Lindsay, Miss Bertha S. Philpotts, and Prof. T. P. Nunn are, according to the University of London Bill recently introduced in the House of Lords by Lord Balfour, to be the first Commissioners of the University of London.

Sir William Beveridge, Director of the London School of Economics, has been elected Vice-Chancellor for 1926-27 in succession to Prof. E. A. Gardner.

Mr. W. C. Clinton has been appointed as from August 1 to the University chair of electrical engineering tenable at University College. Mr. Clinton was educated at the Central Foundation School, the Technical College, Finsbury, and the City and Guilds College. In 1894 he was appointed assistant in the Electrical Engineering Department at University College, and since 1907 has been assistant professor of electrical engineering. His published work includes "Electric Wiring," "The Science of Illumination" (translated and modified from the German of Dr. L. Bloch); and numerous articles in the *Proc. Phys. Soc.*, *Phil. Mag.*, and other scientific and technical papers.

Mr. P. A. Buxton has been appointed as from August 1 to the University readership in medical entomology tenable at the London School of Hygiene and Tropical Medicine. Mr. Buxton was a fellow of Trinity College for the period 1916-21. In 1921-24 he was medical entomologist to the Palestine Government, and in 1924-25 leader of the expedition from the School of Tropical Medicine to the South Pacific. Since March last he has been Director of the Department of Medical Entomology at the London School of Hygiene and Tropical Medicine. He has published a book entitled "Animal Life in Deserts" (London, 1923), and numerous articles in scientific journals.

The title of reader in pharmacognosy in the University has been conferred on Mr. T. E. Wallis, in respect of the post held by him at the School of Pharmacy. Mr. Wallis was educated at Owen's School, Islington (1885-1892), and Birkbeck and King's Colleges (1899-1900). His published work includes "Analytical Microscopy, its Aims and Methods," "Botany: an Outline of Classification" and "Practical Pharmacognosy."

Prof. A. J. Clark, who occupied the University chair of pharmacology at University College, has resigned on his appointment to the chair of materia medica in the University of Edinburgh; Dr. G. V. Anrep has resigned from the University readership in physiology tenable at the same College, on his appointment as lecturer in physiology in the University of Cambridge.

Mr. Major Greenwood has been appointed as from August 1 to the University chair of epidemiology and vital statistics tenable at the London School of Hygiene and Tropical Medicine. The title of reader in medical statistics was conferred on Mr. Greenwood in January 1915 in respect of the post held by him at the Lister Institute of Preventive Medicine. He was Milroy lecturer at the Royal College of Physicians in 1922, and is honorary secretary of the Royal Statistical Society and of the Section of Epidemiology of the Royal Society of Medicine. He has published a number of papers on medical statistics and industrial medicine.

Prof. W. W. C. Topley has been appointed as from August 1 to the University chair of bacteriology and immunology tenable at the London School of Hygiene and Tropical Medicine. Prof. Topley was educated at St. Thomas's Hospital and the University of Cambridge. He was director of the Institute of Pathology at Charing Cross Hospital (1911–22), and since 1922 he has been professor of bacteriology in the University of Manchester and director of the Public Health Laboratories. In 1919 he was Goulstonian lecturer to the Royal College of Physicians, and in March last he delivered the Milroy lectures in experimental epidemiology there. He has published numerous papers dealing with bacteriology, epidemiology, and immunology.

The degree of *D.Sc.* in botany has been conferred on Miss M. H. Carré, the Imperial College (Royal College of Science) and Bedford College, for a thesis entitled "Chemical Studies in the Physiology of Apples."

St. Andrews.—The University Court has appointed Mr. A. D. Peacock, senior lecturer in zoology at Armstrong College, Newcastle-on-Tyne, in the University of Durham, to the vacant chair of natural history in University College, Dundee. Mr. Peacock's experience in the teaching of zoology and in research work, chiefly in entomology, extends from 1909 to the present time, that period being broken by service as an entomologist in the Government Agricultural Department of Southern Nigeria and by military service from 1914 until 1919, when his entomological knowledge was made use of for research and instruction in the Medical and Sanitary Services under the War Office. In this department of investigation he has published many valuable scientific papers. Miss Edith Philip Smith has been appointed to the lectureship in botany in University College, Dundee. Miss Smith, who studied botany at Edinburgh, Oxford, and Harvard, was a lecturer in botany in King's College, London, and has for the past four years been demonstrator in botany in the University of Edinburgh. Her publications include a number of papers embodying the results of research, chiefly in plant physiology. Mr. A. O. Adamson having vacated the post of assistant in natural history in the United College, St. Andrews, on his having been awarded a Commonwealth Research Scholarship, Miss Christina H. Sutherland has been appointed to succeed him.

Dr. H. H. Hodgson has been appointed head of the combined departments of colour chemistry and general chemistry at the Huddersfield Technical College.

Contemporary Birthdays.

July 2, 1862. Sir William H. Bragg, K.B.E., F.R.S.
July 4, 1848. Lord Sydenham, G.B.E., F.R.S.
July 5, 1862. Prof. G. H. F. Nuttall, F.R.S.
July 6, 1857. Sir Hercules Read, F.S.A.
July 6, 1865. Sir Hugh K. Anderson, F.R.S.
July 6, 1873. Mr. Sidney George Brown, F.R.S.
July 8, 1861. Prof. J. Arthur Thomson.

Sir William Bragg, who succeeded the late Sir James Dewar as Fullerian professor of chemistry in the Royal Institution, was born at Westward, Cumberland. Educated at Market Harborough Grammar School, and King William's College, Isle of Man, he graduated at Trinity College, Cambridge, in 1884 as third wrangler. His mathematical studies had been pursued under the guidance of Dr. E. J. Routh. Elected in 1885 to the chair of mathematics and physics in the University of Adelaide, he returned to England in 1908 to take up the professorship of physics in the University of Leeds, transferring, in 1915, to a similar chair in University College, London. In that year Sir William was allotted the Nobel prize for physics, jointly with his son, Prof. W. L. Bragg, for their services in promoting the investigation of crystal structure by means of X-rays. The Royal Society awarded its Rumford medal in 1916 to Sir William, on the ground of his researches in X-ray radiation.

Lord Sydenham, Governor of Victoria from 1901 until 1904, is of Lincolnshire extraction, and he was educated at Haileybury and the Royal Military Academy. Entering the Royal Engineers branch in 1868, he participated in the 'eighties in much active service. Lord Sydenham was president of the British Science Guild in 1917–20.

Prof. Nuttall was born in San Francisco. Since 1906 he has been Quick professor of biology in the University of Cambridge. He has written many memoirs concerning bacteriology, entomology, parasitology, and hygiene.

Sir Hercules Read engaged early in the service of the British Museum, under the inspiring influence of Sir Augustus Franks. He became keeper of British and medieval antiquities and ethnography in 1896, retiring in 1921. Sir Hercules has been twice president of the Society of Antiquaries, namely, for the period 1908–14, and again 1919–24. He is Hon. LL.D. Edin.

Sir Hugh Anderson was born at Hampstead. Educated at Harrow, Cambridge, and, for his medical studies, at St. Bartholomew's Hospital, he has been, since 1912, Master of Gonville and Caius College, Cambridge.

Mr. Sidney Brown, electrical engineer, was born at Chicago, but he is of English parentage. He was educated at Harrogate College, and University College, London. Mr. Brown is responsible for many very ingenious inventions applicable to submarine cables, telephones, airships, aeroplanes, and radio, and also of a gyroscopic compass. He is the author of a number of original contributions to science.

Prof. J. Arthur Thomson was born in East Lothian, and he was educated at the Universities of Edinburgh, Jena, and Berlin. Since 1899 he has been Regius professor of natural history in the University of Aberdeen. He was Terry lecturer at Yale in 1924. Prof. Thomson has written many books on natural history subjects, which have a wide vogue. He is Hon. LL.D. Edin.

Societies and Academies.

LONDON.

Royal Society, June 24.—J. C. **McLennan** and A. B. **McLay**: On the structure of the arc spectrum of gold.—Nearly all the wave-lengths known to belong to the gold arc-spectrum have been classified. The most important wave-lengths not yet classified are six that were found to be absorbed by the vapour in the under-water spark of gold. These wave-lengths undoubtedly involve the metastable term $1D_3^2$. Zeeman-effect experiments will probably furnish the best means of definitely settling any features of the arc-spectrum of gold not yet clear.

J. C. **McLennan** and H. G. **Smith**: On the series spectra of palladium.—The regular arc-spectrum of palladium, involving disturbances of a single electron outside a core of nine 4_3 electrons, includes very nearly all the strong lines of the arc, and most of the faint lines of wave-length longer than 3400 Å.U. In the region of shorter wave-lengths there is also a large number of faint lines, apparently belonging to the arc-spectrum, for which no place can be found in the regular series system. These faint lines can probably be ascribed to a secondary-series system. The analysis of the spark-spectrum has shown that $(4_3)^8\ 5_1$ and $(4_3)^9$ are of almost equal stability, and consequently terms of this type should occur with considerable prominence in the arc-spectrum, but might not combine readily with the regular terms. An attempt to find a clue to this part of the spectrum by means of the inter-combinations has been unsuccessful. Similar configurations are also likely to be prominent in the spark-spectrum.

A. M. **Tyndall** and L. R. **Phillips**: The mobility of ions in air (Part iii.).—Measurements of the mobilities in air containing organic vapours over a range of concentration extending up to saturation show in every case a reduction in mobility by the addition of vapour, though the amount depends upon the constitution of the vapour and the sign of the ion. The gradient of the mobility vapour pressure curve for the negative ion is in general steep at low concentrations, but falls off later. In the case of the homologous series of normal aliphatic alcohols the steepness increases as one ascends the series. Similar effects have been observed for the positive ion, but the initial drop in mobility is much less marked. The relative effects of the various vapours seem to depend upon (1) a 'clustering coefficient' determined by the combined effect of any permanent electric moment and an induced electric moment in the neutral molecule, (2) the effective diameter of the cluster.

L. C. **Jackson**: Investigations on paramagnetism at low temperatures (Part ii.).—Orientated sections of the crystal are suspended in a non-homogeneous magnetic field and the forces exerted on them are measured by means of a Pettersson quartz micro-balance sensitive to 10^{-6} mgm. The magnetic field is produced by a large accurately constructed coil and its value is determined from the current strength and the coil dimensions. Data for the three principal susceptibilities of cobalt potassium sulphate are given for temperatures down to $-100°$ C. The principal susceptibility parallel to the symmetry axis of the crystal is also given for nickel ammonium sulphate and manganese ammonium sulphate. The principal susceptibilities all obey the law $\chi(T+\Delta) = \text{constant}$ over the range of temperature investigated.

Sybil **Cooper** and D. **Denny-Brown**: Responses to rhythmical stimulation of the cerebral cortex.—Electrical and myographic records have been made of movement produced by rhythmical stimulation of the cerebral motor cortex. Rates of 18 to 68 per second were used. In the electromyograms the primary waves follow the rate of stimulation, and secondary waves are at present giving an average total frequency of 120 per sec. The mechanical records show rhythmic tremor corresponding in frequency with rates of electrical stimuli applied to cerebral cortex, even at 68 per sec. This confirms, and extends, to higher frequencies, the original observations of François-Franck and Pitres.

Karl **Pearson**: Researches on the mode of distribution of the constants of samples taken at random from a bivariate normal population.—This paper deals with the distribution in samples, regardless of their size, taken from a large normal population of some of their 'compound' constants By compound constants is meant not simple constants like means, standard deviations, or coefficients of correlation, but functions of these constants. The actual curves of distribution of the standard deviations of arrays, and of the regression coefficient are obtained. Also the distribution of the means of arrays as determined by the regression line of the sample is studied, and all the moments of this distribution are determined, but it has not been possible to determine its curve of distribution. Even when sampling from a normal population, the curves of distribution of compound constants (like those of the majority of simple constants) are not themselves normal, nor are the relations between them linear. It follows accordingly that the so-called 'probable errors' of these constants are of relatively small significance in exactness, especially in the case of *small* samples, where their values are usually given by physicists and astronomers, as measures of accuracy of observation.

Lord **Rayleigh**: Further spectroscopic studies on the luminous vapour distilled from metallic arcs.—The appearance of high series members in the luminous vapour is due to their narrowness. In the arc these lines are so broad as to overlap; as the vapour emerges and expands, they become narrow and can be resolved. Enhanced lines occur in the distilled vapour, though in diminished intensity relative to the arc lines. In some cases, *e.g.* magnesium, they fade out very rapidly compared with the arc lines. The resonance line of mercury $1_1S' - 1p_2$ gains intensity relative to all other lines as the vapour matures. The same is true of calcium; but the corresponding line of magnesium behaves in the opposite manner. A luminous jet of one metallic vapour is able in many cases to excite the vapour of another metal injected into it, but generally only if the ionisation potential of the first metal exceeds the excitation potential of the spectrum line in question.

Sir William **Hardy**: A microscopic study of the freezing of gel (Part i. and Part ii.).

Sir William **Hardy** and Millicent **Nottage**: Studies in adhesion (i.).

T. **Moran**: The freezing of gelatin gels.

W. **Jevons**: The more refrangible band system of cyanogen as developed in active nitrogen.—Modification of the $\lambda 3590$ $(n'' - n' = -1)$ group and of some of the 'tail' bands is discussed. As regards the $\lambda 4216$ and $\lambda 3883$ groups, the afterglow develops especially lines of low m values and bands of high n' values. As n' increases the intensities of the bands in each group tend to show an alternation as well as a general increase. Bands with $n' = 1$ are the weakest. The $\lambda 3590$ group (like the above) is shortened in the low wave-length direction, but (unlike the above) it is prolonged in the high wave-length direction in the afterglow as compared with the arc, and also consists of headless bands. On the

assumption that these bands have $n''-n'=-1$, the absence of heads follows from the non-development of high m lines, and the high wave-length extension is in accordance with the enhancement of high-n' bands.

J. A. V. **Butler**: The equilibrium of heterogeneous systems including electrolytes (Part i.).

(The late) Mrs. Hertha **Ayrton**: Primary and secondary vortices in oscillating fluids: their connexion with skin friction.—Mrs. Ayrton demonstrated the existence of pressure differences on the lee side of obstacles in oscillating water and showed that vortices were formed in the liquid. These vortices were called 'primary' vortices when their full strengths were attained in one oscillation, and 'residual' vortices when more than one oscillation was required for their full development. The word 'secondary' is now substituted for 'residual.' Instantaneous photographs show that primary vortices occur near the ends of a tank in which water is oscillating and also near the nodes of stationary waves in such a tank, whilst secondary vortices spread throughout the remainder of the water.

T. T. H. **Verschoyle**: Isotherms of hydrogen, of nitrogen and of hydrogen-nitrogen mixtures at 0° and 20° C. up to a pressure of 200 atmospheres.—Experimental determination of isotherms of binary mixtures has been limited almost exclusively to mixtures of oxygen and nitrogen. It appears to be tacitly assumed that, for mixtures of the permanent gases, pv-values at normal temperatures are linear functions of composition. Isotherms of three mixtures of hydrogen and nitrogen have been measured at 0° and 20° C., and the results prove that the pv-values for the mixtures are far from being linear functions of the composition. Actually, a small admixture of nitrogen with hydrogen has relatively little influence on the pv-values, whereas a small addition of hydrogen to nitrogen has a comparatively great effect.

E. W. **Marchant** and J. L. **Miller**: The loss of energy in metal plates of finite thickness, due to eddy currents produced by alternating magnetic fields.—The energy lost due to eddy currents, produced by an alternating magnetic field, due to a flat circular coil, when placed near metal plates of different thicknesses, reaches a maximum for a certain thickness of plate. With a frequency of 50 cycles the loss is a maximum with copper plates about 0·4 cm. thick. A similar effect has been observed with zinc plates, though the maximum is not so definite. The mathematical theory worked out by Prof. Proudman is consistent with these results. The shape of the curve of the magnetic field is assumed to approximate to a Bessel function of zero order; a new integral is given for determining magnetic fields due to a coil of wire in terms of Bessel functions.

W. **Sucksmith** and H. H. **Potter**: On the specific heat of ferro-magnetic substances.

L. B. **Pfeil**: The effect of occluded hydrogen on the tensile strength of iron.—Tensile tests during electrolytic pickling of carbon-free iron are discussed. With iron in the ordinary finely crystalline condition, occluded hydrogen may result in a 10 per cent. reduction in tensile strength and an 80 per cent. reduction in elongation: the fracture, instead of passing *through* the crystals, as is normally the case, may pass only *between* the crystals. With single crystals, occluded hydrogen does not appreciably affect movement on the slip planes, but it materially decreases the cohesion across the cubic cleavage planes, the cohesion in certain cases being reduced to 5 tons per square inch. When the parallel portion of a test piece is made up of two large crystals, the weakest point is, in general, the intercrystalline boundary; the strength here is only about half that of the boundary between small crystals. The difference is due to the irregular path of the intercrystalline fracture in finely crystalline iron.

T. E. **Allibone**: The infra-red secondary spectrum of hydrogen.

D. C. **Rose**: The scattering of alpha particles through small angles.—The single scattering of alpha particles through angles from 1°·2 to more than 8° has been measured. A nearly parallel beam of alpha particles was projected perpendicularly on a thin gold foil and the number of particles emergent at the different angles was counted. The relative number of particles scattered at the different angles show that the nuclear field obeys the inverse-square law of force fairly closely, for distances between $0·4 \times 10^{-10}$ cm. and $1·7 \times 10^{-10}$ cm. from the nucleus. This region includes the K shell of electrons (radius, $0·69 \times 10^{-10}$ cm. for gold) calculated from Bohr's model of the atom. Other experimenters have shown that the nuclear field obeys the inverse-square law of force for distances between $0·5 \times 10^{-10}$ cm. and $3·2 \times 10^{-12}$ cm. from the nucleus. The absolute number of particles scattered show that over the same range the field corresponds to a nuclear charge within 5 per cent. of the atomic number times the elementary electronic charge. The results are not accurate enough to detect the shielding effect due to the K shell of electrons. The curves indicate that the K shell is not ionised to any appreciable extent. Wentzel's criterion for single scattering has been extended.

V. H. **Stott**, D. **Turner** and H. A. **Sloman**: Effects of thermal treatment on glass as shown by precise viscometry.—A new viscometer for molten glass has been designed; prolonged measurements can be made on the same specimen subjected to various heat treatments. The determination depends on the thickness of glass which adheres to a thin iridio-platinum wire withdrawn from the glass at a known velocity. The apparatus is capable of a precision of the order of $\pm$ 3 per cent. of the viscosity, which is equivalent to a temperature error of about 3°. At sufficiently high temperatures the viscosity of a particular glass is a function of temperature only. Below 1200° the glass is generally in a heterogeneous form yielding discordant viscosity values; the heterogeneity is not directly connected with devitrification, which takes place at approximately 950°. The glass, in its high-temperature state, may be cooled to room temperatures and reheated an indefinite number of times without change of state if the cooling and heating be not too slow.

J. E. **Lennard-Jones** and Miss B. M. **Dent**: The forces between atoms and ions (ii.).—Earlier results are extended to provide a complete table of forces between the monovalent and divalent ions of the inert gas type.

J. **Topping** and A. E. **Ludlam**: Tables of log $K_0(x)$ over the range $x=2$ to $x=12$ at intervals of 0·001.

B. **Lambert** and K. T. **Hartley**: An investigation of the effects of variations in the radiation factor on the efficiency of Dewar vessels.—The rates of evaporation of liquid oxygen and cooling of hot water have been determined in special Dewar vessels, with one or both of their vacuum-adjacent surfaces silvered, and with polished deposits of silver, gold, platinum, and copper on the vacuum-adjacent surface of the inner vessel, the outer vessel being plain glass. The result obtained by silvering the inner vessel only is almost as good as that obtained by silvering both surfaces. Silvering on the outer vessel only reduces

the efficiency by about a half. With different metal surfaces on their inner vessels, the order of efficiencies of the vessels should be that of the emissivities of these metals. This is the case for all the vessels with respect to hot water—the order being, silver, gold, copper, and platinum—but for liquid oxygen the copper-coated vessel is the least efficient. The dominant wave-length at the temperature of liquid oxygen approaches that corresponding to the 'characteristic frequency' of copper. For energy in this region of wave-lengths the emissivity of copper will therefore be high, so that copper vessels will necessarily be inefficient as containers for liquid oxygen.

J. E. **Lennard-Jones** and W. R. **Cook**: The molecular fields of hydrogen, nitrogen and neon.

H. **Florey**: Observations on the resolution of stasis in the finer blood-vessels.

T. S. P. **Strangeways** and Honor B. **Fell**: Experimental studies on the differentiation of embryonic tissues growing *in vivo* and *in vitro* (ii.). The development of the isolated early embryonic eye of the fowl when cultivated *in vitro*.

Nesta **Ferguson**: The Aloinæ—a cytological study, with especial reference to the form and size of the chromosomes.

Optical Society, June 10.—L. C. **Martin**: The distribution of light in elementary optical images. A series of calculations have been made on the distribution of light near the 'star focus' of a centred lens system in the following cases: (*a*) Freedom from aberration, (*b*) primary spherical aberration, (*c*) zonal spherical aberration. In the two latter cases the condition chosen is that when the least residual phase differences amount to $\pi/2$. The characteristic extra-focal effects are determined, and the effect of primary spherical aberration is discussed. In the case of zonal aberration the greatest axial intensity is not found at the focus giving least phase residuals. In both cases of aberration a concentration closely resembling in some respects the 'Airy' disc characteristic of zero aberration is found.—T. **Smith**: (1) The stationary value of axially symmetric functions. The formula for the stationary value of a function is put into a form which shortens the calculations involved in applying it to functions which possess special kinds of symmetry, such as that corresponding to symmetry about an axis. (2) Note on the criterion for the best position of focus. The position in which the amount of energy within the first dark ring of the diffraction image of a point is a maximum is suggested as not unlikely to correspond with the best focus found by visual observation in the presence of moderate amounts of aberration.

PARIS.

Academy of Sciences, May 25.—L. **Lecornu**: The rotating millstone.—P. A. **Dangeard**: Researches on the cellular formations contained in the cytoplasm of the Peronosporæ.—Alfred **Rosenblatt**: Algebraical varieties of three dimensions of which the types satisfy the inequality $P_g \leqq 3\,(p_g - p_a - 3)$. — Pierre **Humbert**: The q-harmonic functions in hyperspace.—R. **Gosse**: On a note of M. Lainé.—**Goursat**: Remarks on the preceding communication.—Georges **Valiron**: Meromorph functions without asymptotic values.—A. **Toussaint** and E. **Carafoli**: Contribution to the study of the plane flow of fluids. A new mode of applying the coloured thread method possessing certain advantages over that previously used (Marey, Hele-Shaw). The paths can be followed by the kinematograph.—Albert **Nodon**: A colloid condenser. This condenser is composed of two sheets of aluminium separated from each other by a material such as canvas, the pores of which are filled up with a thick paste of colloidal ferric oxide and glycerol. This arrangement fulfils the functions of an electrostatic condenser of great capacity, when submitted to an alternating current.—R. **Forrer**: The structure of the atomic magnet. Demonstration of the existence of a doublet in nickel.—H. **Mineur**: The theory of the partial entanglement of the ether.—W. **Kopaczewski** and W. **Szukiewicz**: The periodicity of colloidal reactions.—Jean **Barbaudy**: The miscibility, densities, and refractive indices of mixtures of methyl alcohol, benzene, and water.—P. **Chevenard**: The dilatometric anomaly of the paramagnetic nickel-chromium alloys; an alloy suitable for an expansion pyrometer. The nickel-chromium alloy suggested in an earlier communication as suitable for use in a pyrometer shows an anomaly at the temperature of 550° C. To remove this anomaly it is sufficient to increase the amount of manganese, to incorporate a small percentage of iron, and to replace a part of the chromium by tungsten. The new alloy (commercial name Pyros), besides nickel, contains 7 per cent. chromium, 5 per cent. tungsten, 3 per cent. manganese, 3 per cent. iron.—Raymond **Quelet**: The synthesis of derivatives of para-bromoallylbenzene.—A. **Kastler**: Contribution to the study of pollucite. The pollucite examined proved to be non-radioactive and contained 30·5 per cent. of cæsium.— —**Legrand**: A relation between the amplitudes of the annual rise of the Nile, the Niger and the Mekong.—J. **Lacoste**: Earthquakes observed in central France in 1925. Seven earthquakes were noted, the more important being on September 26, December 3 and 9. Details are given of the three mentioned.—Armand **Renier**: The existence of coal balls in the coal basin of Asturia.—J. **Giaja** and X. **Chahovitch**: The inefficacity of pilocarpine to affect the energy metabolism in the absence of the suprarenal capsules.—A. Vedel **Tåning**, The position of the cephalic disc in the Echeneideæ in the course of ontogenesis.—Ph. **Joyet-Lavergne**: The vital colorations of the gregarines and the characters of sexualisation of the cytoplasm.—Y. **Manouélian** and J. **Viala**: The enhancement of the virus of rabies and the Negri bodies.

ROME.

Royal National Academy of the Lincei, April 18.—Leonida **Tonelli**: Quadrature of surfaces.—A. **Angeli**: Anomalies of certain reactions. A number of cases are quoted in which a reaction of one substituent group in an organic compound may be retarded or even prevented by the introduction into the compound of another substituent.—Federico **Sacco**: The tunnel at Drink (Valle d'Aosta).—Achille **Russo**: The ex-conjugants derived from the first accessory conjugation between impure gametes in *Cryptochilum Echini* produce pure gametogens and pure gametes, which renew the principal cycle.—Alessandro **Weinstein**: The speed of propagation of the solitary wave.—Giorgio **Vranceanu**: Dirichlet's theorem.—Arnaldo **Masotti**: An extension of Blasius's formula.—Eligio **Perucca**: The cause of 'flying shadows.' If the phenomenon of flying shadows is one of diffraction, it must be more complicated and more indirect than is indicated by Armellini's theory. The absence of chromatism and the velocity with which these shadows are propagated suggest that the cause should be sought in the earth's atmosphere.—Enrico **Fermi**: The intensity of prohibited lines in intense magnetic fields.—Franco **Rasetti**: The polarisation of the light emitted by electronic shock.—Giorgio **Piccardi**: Ionisation potential of silver. By means of the flame method of Rolla and Piccardi, values ranging from 7·37 to

7·67 volts are obtained for the ionisation potential of silver, the mean being 7·46 volts. In view of the inaccuracy introduced by the impossibility of avoiding slight sparkling of the fused metal, this result agrees satisfactorily with the value, 7·54 volts, derived from the limits of the spectral series.—Carmela **Ruiz**: New investigations on barytes from Racalmuto, Sicily. Measurements of two specimens of barytes, occurring together with calcite and sulphur at Racalmuto, gave the axial ratios, $a:b:c = 0{\cdot}81558:1:1{\cdot}31467$, and the density 4·42-4·43 at 18°-19°.—Gustavo **Cumin**: Geological observations on the island of Asinello and on neighbouring rocks (Carnaro). The island of Asinello and the neighbouring rocks are mostly Cretaceous, Eocene measures appearing only on the principal island. Their coast morphology is the result of an aerial erosive action, on to which the marine action has been superposed.—F. Stella **Starrabba**: Monthly distribution of the eruptions of Japanese volcanoes.—Giulio **Cotronei**: Dark and light fibres in the insular organ of *Petromyzon marinus*.—B. **Monterosso**: The structure of the body of *Peroderma cylindricum* Heller, in relation to the cellular theory.

Reconstitution of the University of London.

THE Government has redeemed its pledge to introduce legislation "to make further provision for the University of London." The University of London Bill, which, on the motion of the Earl of Balfour, was accorded its second reading in the House of Lords on June 29, proposes to appoint eight commissioners with plenary powers to draft statutes for the University "in general accordance" with the recommendations contained in the Report of the Departmental Committee of the Board of Education appointed by Mr. Trevelyan in 1924, subject to any modifications which may appear to them to be expedient. Thus the procedure is assimilated to that adopted in the recent reconstitution of the Universities of Oxford and Cambridge. There are, however, important differences between the two cases. Whereas the reconstitution of the ancient universities was based on the recommendations of a Royal Commission of great authority, presided over by Mr. Asquith (now Lord Oxford)—recommendations which were unanimous save for some relatively unimportant reservations by individual members—the proposed reconstitution of the University of London is to be based, not on the recommendations of the Royal Commission, generally known as the Haldane Commission, which reported in 1913, but on the recommendations of a Departmental Committee of the Board of Education. Conditions, it is true, have changed since the Haldane Commission reported. The reception accorded to the Departmental Committee's report has been comparatively friendly, but it cannot be overlooked that the constitution proposed by the Committee differs essentially from that suggested by the Royal Commission.

Another difference relates to the historical development of the universities in question. Broadly speaking, Oxford and Cambridge have retained their traditional constitutions, based on the University of Paris. They remain corporations governed by their graduate members. Certain internal reforms, such as the abolition of the celibacy of college fellows, have been effected by the pressure of public opinion. But external control in any form has always been resisted, notwithstanding acceptance of generous financial aid from the Government. The presence of outside representatives on the Council, the Royal Commission reported in 1922, "would hamper the Council in its work without securing as a rule any compensating advantage"; and the objection to representatives nominated by the Government appeared to the Commission "particularly strong."

The University of London was established by Royal Charter in 1836 with a Senate nominated by the Government to administer its educational affairs, the Government retaining full financial control. It was not until

1858 that the graduates secured a share in the administration of the University, when the privilege of nominating for a limited number of seats on the Senate was conceded to Convocation under a new charter. Forty years later the teachers of the colleges and medical schools in London were accorded a similar privilege, the Act of 1898 reconstituting the University as a teaching university. The reconstitution now under discussion in Parliament derives its motive force from the demand of the Government, voiced by the University Grants Committee, for an improved financial and executive control.

The schedule of the University of London Act of 1898 gave to the Commissioners named in the Act detailed directions for the constitution of the Senate. It enforced the 'advisory' character of its chief councils, provided safeguards for religious and sex equality, prescribed the radius for the recognition by the University of public educational constitutions, insisted that the internal and external degrees of the University should represent "as far as possible the same standard of knowledge and attainment," and gave instructions on several other matters. These provisions were fully discussed by Parliament. If the present Bill passes, Parliament will abrogate its right to discuss the details of academic organisation, reserving only the right to reject statutes. Government of a university by statutes without rigid and permanent directions from Parliament offers certain obvious advantages, provided fundamentals are safeguarded. Statutes can be amended to meet changing conditions without cumbersome Parliamentary procedure. Under the present Bill, statutes for the University can be altered or supplemented by the University, except statutes, if any, that the Commissioners may consider ought not to be altered by the University. The Bill directs the Commissioners, before adopting statutes, to receive representations "by or on behalf of the Senate or Convocation or any fifty graduates of the University, or by or on behalf of any other bodies or persons appearing to the Commissioners to be directly affected by the proposed statute"; and there are the usual provisions for the approval of statutes by the Privy Council. Thus the arrangements for publicity and for preliminary discussion by those specially qualified are adequate.

This is not the occasion for a detailed discussion of the recommendations of the Departmental Committee, either at large or in relation to the promotion of scientific education and research. Controversy has so far centred—as was to be expected—round the status and powers of the proposed Council which is to be given financial and executive control. This reform is fundamental; but the question of the relation of the Council to the Senate, the body responsible for educational policy, will have to be closely examined by the Commissioners. Presumably all the proposed Commissioners are already in agreement as to the creation of the Council. On other matters, the Commissioners can adopt modifications of the Departmental Committee's recommendations, and no doubt many suggestions will be forthcoming in due course in regard to such matters as the number and mode of election of heads of colleges as members of the Senate, the devising of some method more dignified than co-option of appointing a number of members of the Senate as independent experts or on grounds of services rendered to the University—the elder statesmen or aldermen of the University—and the appointment of the Principal as a member of Senate and Council *ex officio*. Statutes should also authorise the payment of fees to members of the Council, thus emphasising the serious nature of their duties and the demands on their time and energy.

The important question of the relation of the University to its affiliated colleges is a matter which will be within the competence of the Commissioners, who may make statutes for the colleges, subject to the consent of the respective governing bodies. Their powers appear to extend to the incorporation or disincorporation of colleges in the University, a subject of acute controversy within the University. Under the present statutes, colleges were affiliated to the University without any clearly defined privileges and obligations, and it will be of great advantage both to the University and to its colleges if their relations are placed on a firmer basis.

The personnel of the Commissioners has been selected with care and judgment. The chairman, Mr. Justice Tomlin, will ensure judicial treatment of the questions to be considered. Two graduates of the University, Sir Josiah Stamp and Prof. T. P. Nunn, and the present Principal Officer, Sir Cooper Perry, who will retire from his University office shortly, may be deemed to represent the University. The point of view of the Board of Education and the London County Council will be represented by Sir Amherst Selby-Bigge, the late Secretary of the Board, and Sir Cyril Cobb respectively. Oxford contributes a representative in the Master of Balliol (Dr. A. D. Lindsay), and the special interests of women will find a natural protector in Miss Philpotts.

Past history has shown that the University of London through its graduates can exercise powerful political influence. Will that influence be used on the present occasion against the Bill? Convocation, at a sparsely attended meeting held during the strike, adopted three resolutions declaring that the creation of a Council to control the finances of the University would have

"prejudicial effects upon the University"; that the reconstitution of the Senate in accordance the mmendation of the Departmental Commission would be "a grave error"; and, finally, strongly deprecated the setting up of a Statutory Commission. The Senate has adopted a resolution declaring its opinion that as regards the relative positions of the Council and the Senate, the scheme proposed by the fajority Report of the Departmental Committee should rejected on the ground that it will be found to be workable in practice, that it will deprive the truly resentative body (the Senate) of all effective control, t it will not clear the body charged with control of ance from any possible imputation of partiality; and lly, that it will complicate further the already too plicated machinery of the University. The Senate her offered to submit a scheme of agreed reforms. inference to be drawn from this resolution is that Senate would prefer that the Council, if created, ld have the status of a statutory finance committee. ne final suggestion. Would it not be well for the ernment to make some announcement as regards eased financial aid for the work of the University, nd when reconstituted? The great developments in iversity education, which London, as the capital of Empire, urgently needs, cannot be accomplished, vever perfect a constitution may be provided by authority of the Government, unless the money is thcoming. The University may reasonably expect Government, which has shown so much solicitude its spiritual welfare, to contribute generously to its terial needs.

T. LL. HUMBERSTONE.

Eugenic Reform.

Need for Eugenic Reform. By Leonard Darwin. Pp. xvii + 529. (London: John Murray, 1926.) 12*s.* net.

HIS is in every respect a notable book by a most distinguished author. Major Darwin has now or fifteen years occupied the presidential chair in the Eugenics Education Society, and comparatively few ealise the services which he has rendered towards naking clear the social implications of the results of he scientific study of heredity. The word 'Eugenics' ignifying 'the study of the agencies under human ontrol by which the human stock can be improved' vas coined by Galton, as most people know. Most are lso aware that it was associated in the public mind vith a number of fantastic projects for the compulsory nating of specially selected specimens of opposite exes in order to improve the race. For this concepion of the subject Galton is directly responsible; it has ed to eugenists being regarded as a collection of faddists, and has drawn on to the whole subject the sharpest shafts of ridicule and sarcasm. G. K. Chesterton has said of eugenic reform that it could be imposed only on slaves and cowards, and it is, no doubt, of 'Galtonian' reforms that he was thinking when he made this statement.

The present reviewer is forced to confess that he formerly shared the common attitude towards the subject, an attitude which, as he must regretfully admit, is still maintained by some of his most admired scientific friends. It was in 1913, when he had the good fortune to listen for the first time to a presidential address by Major Darwin, that the reviewer first saw that a wholly different interpretation could be given to eugenic reform, an interpretation calculated to appeal strongly to the common sense of all who take the trouble to give their attention to the subject. This interpretation, which, though theoretically admitted, was not regarded as of practical importance in comfortable Edwardian days, is now forcing itself on the attention of every one who has to deal with social affairs. Major Darwin pointed out that, if we went on fostering the unrestricted multiplication of the least competent members of the nation by continually increasing doles extracted from the pockets of the more competent and therefore well-to-do, we should inevitably lower the quality of the race. It is a sinister portent that the large families which were reared in our rectories and in the manses of Scotland in Victorian days, from which we gathered so many distinguished and able men, have disappeared, whilst there is no serious diminution in the offspring of our dock labourers and unskilled workers. Major Darwin's conception of eugenics was essentially the extension of his father's doctrine of natural selection to human affairs.

The book which we are considering opens with a biological introduction which deals with the Mendelian theory of heredity and discusses the inheritance of acquired qualities and the Lamarckian theory of evolution. This part is by far the weakest section of the book, for Major Darwin labours under the disadvantage of not being a biologist, and this disadvantage is increased by the fact that, as he admits in the preface, he has relied for assistance and advice mainly on Mr. R. A. Fisher and Mr. C. B. S. Hodson. Of these the first is a mathematician, and the second name is obviously a slip for Mrs. Hodson, the respected assistant secretary of the Eugenics Education Society, who undoubtedly has had some training in biology, but is scarcely fitted to give serious criticism in this subject.

Major Darwin accepts the extreme Mendelian view, namely, that the whole force of heredity in any individual is capable of being analysed into a series of units or 'genes,' and that a chance assortment of 'genes' is

handed on by the parent to his children. This view, which has been rejected by many biologists with a really wide outlook on the science, including systematists, embryologists, and palæontologists, leads, if logically pressed, to impossible and absurd conclusions. The innate common sense of Major Darwin leads him to see this: he plaintively confesses that if genes are unalterable he cannot see how evolution can ever have taken place, for all the genes which make up human heredity must have been present in the original amœba. It may be added that the 'factorial analysis' of heredity adds nothing to our knowledge of the subject: the 'genes' or 'factors' are purely imaginary units, and the number is continually added to as Nature shows herself unwilling to be compressed within mathematical formulæ. As the author naïvely confesses, it is impossible to devise means of analysing human capacities into genes, and eugenic reform cannot wait whilst the attempt is made; therefore Mendelism is of service to eugenics chiefly by fostering belief that heredity is not a haphazard thing but follows fixed rules. But this belief is far older than Mendelism; no farmer, nor even any common-sense observer of human affairs, needed Mendel to teach him this; it is expressed in unequivocal language by the Founder of Christianity himself: "neither can a corrupt tree bring forth good fruit."

Major Darwin is no happier in his criticisms of Lamarckism. He points out that there are certain qualities which he does not think could have been 'acquired' in this sense by animals; as, for example, the protective resemblance shown by the plumage of a bird. How, he asks, could the bird know when its plumage assimilated with its surroundings? Well, we do not know how a bird would react to changed surroundings, but we do know that many reptiles, amphibia, and fishes can and do control their colour so as to make it match their environment, and that this control is exercised through the eye. If Major Darwin will keep a common frog in a dark tank he will find that it soon assumes a very dark brown tint. If it is now removed to a white porcelain dish it will in half an hour assume a light straw-coloured tint. If, however, the optic nerves of the dark frog are severed, it will remain dark on the whitest porcelain. What goes on in the mind of the frog, what it feels or thinks, neither Major Darwin nor any one else knows.

Then Major Darwin says that whilst doubtless a muscle increases in size with use, Lamarckians have never explained how this power was 'acquired.' On this subject it is necessary to speak firmly and decisively. Neither Lamarck nor any other competent biologist has ever advanced a theory to explain how living beings could develop out of dead matter. The fundamental properties of life are as clearly manifested in amœba as in man; every faculty shown in the higher forms of life is present in the simplest form in germ—*ex nihilo nihil fit*. These properties are the presupposition of every valid theory of evolution. This was clearly seen and expressed by no less a person than Alfred Russel Wallace. The author's third objection that Lamarckian change, if it really occurs (and his father admitted that it did), is extremely slow in its action and can therefore be left out of account in considering eugenic measures, has a considerable measure of truth in it; yet even here a *caveat* must be entered. It is not the case that "millions of years" are needed to effect any noticeable change. It is not "millions of years" since palæanthropic man ranged over Europe, and yet since that time we have acquired straight backs and thighs. The Lamarckian view is that evolution is due to changes of habits (in Lamarck's phrase, the effort to satisfy new needs awakened by new surroundings), and that these habits induce changes in structure which are passed on to the next generation. The first stage in this transmission consists merely in a quickened response to the same stimulus which induced the corresponding change in the parent. It is only after a long time that the change becomes so engrained in the constitution that it appears without the stimulus at all. Baron Nopčsa, in a recent brilliant address to the London Zoological Society, pointed out that in the adaptations which fit the human leg to maintain the upright position both stages can be found. The thickened pad on the sole of the foot appears whilst the embryo is in the womb, but the change in the ankle-joint only appears after walking has begun, and fails utterly to appear if the foot for any reason is not used. It is quite probable that good education—the development of the brain by mental exercise, not the cramming of it with facts—does leave in the progeny of the educated an increased capacity to learn.

Besides Lamarckian adaptation, however, which being an epitome of the past history of the species, accounts for the racial differences which divide mankind, there is another kind of variation prominent amongst our domestic animals which also occurs largely amongst civilised city-dwellers, who, like the denizens of the farmyard, are domesticated. This is a weakening of developmental energy caused by bad conditions surrounding the germ in its earliest period of growth. This weakening produces a disharmony in growth which results in weird structural aberrations, and once produced it is handed on to subsequent generations and produces the same result in the progeny as in the parents. To this cause not only the 'fancy' character of our domestic breeds but such pathological aberrants as epileptics and mental defectives owe their origin. Nevertheless, if such individuals are transferred to

healthy natural surroundings *and left to support themselves by their own efforts,* this plasma-weakness gradually passes off and the natural structure is regained. A beautiful example of this reversion can be seen every day in London; and it is one which seems to have been going only for forty or fifty years, since it is never mentioned in the works of Charles Darwin, and it would have greatly interested him had he seen it. As all know, pigeons originally escaped from dove-cotes have multiplied all over London and maintain themselves in our squares, no doubt in the innocence of their hearts mistaking our tall London houses for their ancestral cliffs. A large proportion of these pigeons are assuming the plumage and shape of the wild rock pigeon, yet this is certainly not due to crossing, for the wild progenitor is now an exceedingly rare bird and is in fact almost extinct. So the emigration of a city-stunted population to Australia, if they were not coddled but left to their own efforts, might in time give rise to a population of respectable physique.

The author, as in filial duty bound, attaches great importance to natural selection--and so do we. If advance is the result of energy and vigorous striving, a race will progress only as the weak and lazy are eliminated or, at any rate, prevented from procreating progeny --and in this lies the central core of all Major Darwin's proposals. He points out the disastrous effects of public assistance; the class assisted does not increase in its efforts at self-maintenance, but depends more and more on doles; and it increases in fertility whilst the class from whom assistance is drawn diminishes in numbers. He then considers how the elimination of the less worthy class might be promoted. He considers, and rightly so, that parenthood should be prevented in the case of all certifiable as mentally defective. This ould be accomplished if lifelong segregation were nstituted with the acceptance of voluntary sterilisation and freedom as an alternative. He thinks that parenthood should be prohibited even in cases where the nental defect is held to be due to 'environmental factors,' since even if such parents would not hand on he defect to their children—and we consider it very probable that they would do so—they are quite unfit to give parental care and good upbringing. Major Darwin discusses the objections to sterilisation which are both futile and sentimental. It is objected that sterilised individuals would feel free to adopt an immoral life. This, we might rejoin, is not our business: they are in no way forced to do so, and even if they did, his would be a very much lesser evil than the contamination of the next generation by them. After all, people who now desire an immoral life are deterred not by the fear of illegitimate offspring, but the dread of venereal disease; yet that is no argument against stamping out that disease if we can. The author would further sterilise or segregate the habitual criminal, and when hard necessity has made us shed some of our sentimentalism we shall agree with him. As he remarks, 120,000 new recruits join the ranks of labour every year, and yet it seems probable that our trade will never rise to its pre-War level, so that some regulation of population is an absolute necessity.

This necessity, it seems to us, can only be met by birth-control; that is, limitation of size of family. Here, however, the author shows himself fussy: he is afraid that contraceptive measures in certain circumstances might do harm. The answer to this is that since contraceptive practices are widespread amongst the more intelligent members of the community, to extend the knowledge of them amongst the class that is multiplying too quickly can do no harm. Of course, as Major Darwin sees, this would leave the utterly reckless class uninfluenced. So the right of any one to have children whom he cannot support must be challenged sooner or later, and the ultimate remedy for that is the threat of sterilisation if the family is added to. It seems to us that another remedy not envisaged by the author would be to treat all public assistance as a loan which must be repaid before the beneficiary is allowed to vote.

Major Darwin then goes on to discuss mate-selection, divorce, and kindred matters. On the question of divorce he is stern and conservative. Like all eugenists, he considers marriage as an institution mainly for the purpose of the next generation and family life as indispensable, and this life would inevitably be destroyed by easy divorce. As to mate-selection, no doubt prudence should be exercised in selecting a wife, both with regard to health and character, but as the author truly remarks, love laughs at locksmiths, and once passion is aroused, prudence is apt to be thrown to the winds. Hence, where care ought to be exercised is in the quality of the opposite sex with which our children are familiarised during their young and formative years, for this quality will create the ideals which will arouse passion later on.

The conclusion of the volume is naïve and surprising. The author having come to the conclusion that 'science,' as he conceives it, leads to a mechanical conception of the universe and causes him to regard his fellow-being as an automaton, and as therefore having no individual rights as compared with the welfare of the race, yet finds, when he looks within, that he is a being with a free-will; and so he rejects the conclusions to which 'science' leads him. This he regards as an antinomy which he is powerless to resolve. It might perhaps have induced him to inquire whether the postulates of his 'science' were not doubtful; whether, in fact, we

of the order. The first main section of the book is devoted to ontogeny, or individual development, from fertilisation of the egg to the eclosion of the imago. With regard to oviposition certain remarkable facts are alluded to. It appears that *Polyommatus rutilis* consistently lays its eggs in pairs, one egg of the pair producing a male and the other a female. There appears, furthermore, to be an alternation of male- and female-producing eggs in the ovarioles. With regard to *Papilio memnon*, some of the eggs are laid in pairs and others singly; the eggs in pairs produce male insects, while the isolated eggs give rise to females. In discussing parthenogenesis, the Psychid moth *Solenobia triquetrella* F. is mentioned as reproducing by this method in northern Germany, while in the southern form of this species fertilisation is the invariable rule.

The second section is concerned with the life of the imago. A very full account is given of the significance and distribution of the various types of scent scales and tufts that are so frequent among Lepidoptera. Some reference is also made to the presumed chemical nature of the odours produced. Senses and tropisms are likewise discussed at length, and there is a useful summary of what is known concerning the tympanal organ, mainly through the work of Eggers.

The third section, which extends to more than 240 pages, will commend itself to the general biologist. Here the author elaborates his views on geographical distribution, dimorphism, coloration, mimicry, etc. Certain of the conclusions that are arrived at are not convincing, such as the following. Large-sized species are more generalised than small-sized; the spring generation of seasonally dimorphic forms is more primitive than the summer brood; the lengthier the feeding period of larvæ and the shorter the pupal instar is an indication of primitiveness. With reference to the significance of colour patterns the classification of Heikertinger is followed, and we note in the discussion on mimicry there appears to be no mention of the name of Poulton.

The long chapter on leaf- and other miners is particularly good, and the author adopts a convenient terminology indicative of the different kinds of mines produced. The relations of Lepidoptera to ants and termites likewise form the subject of a separate chapter, and in this connexion the absence of any reference to the remarkable Lycænid *Liphyra brassolis* is unexpected. Further on in the book coloration is dealt with, both from its environmental and experimental aspects, while hermaphroditism, intersexuality, hybridism, all come in for discussion, along with other subjects too numerous for separate mention.

The bibliography at the end of the volume is intentionally restricted but it is too short to be an adequate guide to the literature. We miss reference to a number of leading authorities through the book, while many authors are quoted with no indication other than the date as to where their work is published. In whatever features one may disagree, however, they are insufficient to obscure the outstanding merit of the book.

A. D. IMMS.

Our Bookshelf.

Practical Hints to Scientific Travellers. Edited by Prof. H. A. Brouwer. Vol. 1. Second, revised edition. Pp. v+122+9 plates. Vol. 2. Second, revised edition. Pp. v+150+7 plates. Vol. 3. Pp. v+185+6 plates. (The Hague: Martinus Nijhoff, 1925.) 5 guilders (8*s.* 6*d.*) per volume.

THE object of this work is explained by its title. It consists of a series of independent articles, each dealing with a more or less remote portion of the earth, and written by a man with years of field experience in that particular region. The contributors include representatives of several nations; most of them are well-known geologists, whose names are sufficient guarantee that full reliance can be placed on the advice that they give. All except two of the articles are in English; those two, on Indo-China and Morocco, being in French.

Of the three volumes now to hand (the first two of which are in their second edition), vol. 1 deals with the East Indies and South and East Africa; vol. 2 with various Arctic countries, and with Turkestan; and vol. 3 with Mexico, Indo-China, India, New Zealand, New Guinea, and Morocco. In some of the articles the treatment is much more detailed than in others, but from most of them information on the following subjects is obtainable: preliminary studies and arrangements, climate, means of transport, appropriate equipment, native servants, food-supply, and medical care. Various hints are given concerning the etiquette and idiosyncrasies of the native inhabitants, upon whose attitude the smooth running of expeditions in many lands will largely depend.

Any one about to visit one of the regions here dealt with on a survey or other scientific expedition can be recommended in all confidence both to study this work as a preliminary and to take it with him. He will not fail to derive many useful hints from a perusal, not only of the article relating to the particular country he is visiting, but also of those dealing with other comparable lands.

A Synopsis of the Families and Genera of Nematoda. By Dr. H. A. Baylis and R. Daubney. Pp. xxxvi+277. (London: The British Museum, 1926.) 10*s.* 6*d.*

THE Nematoda as a zoological division contains free-living as well as parasitic forms, and the number of the former is probably as great as, if not greater than, that of the latter. Yet the study of the parasitic forms, owing to their growing interest in relation to disease, has become more and more divorced from that of the free-living. The authors regard this growing separation

as indefensible and they have incorporated both groups in one system of classification. However sound this may be in theory, the result as shown in this volume is somewhat incongruous. The Nematoda are assembled into five orders in all, and the whole of the vast and varied assortment of free-living worms is included with Ascaris and Oxyuris in the single order Ascaroidea.

Apart from questions of classification, however, upon which there is much present-day difference of opinion, the work will prove a trustworthy and succinct guide to the various genera of roundworms together with the habitat usually taken up by the species of each genus and the name of its typical species or genotype. Under each genus is listed the papers most useful for reference. The general arrangement of the volume is admirable and should form a boon to the specialist; as, however, it does not list species, its use to the general reader is unfortunately limited. The year 1923 has been chosen as the closing date for the admission of new genera to the volume, and although a few names made since that date have been included, these are limited to synonyms of earlier genera or to new names to replace those already preoccupied.

The Fauna of British India, including Ceylon and Burma. Edited by Sir Arthur E. Shipley. (Published under the Authority of the Secretary of State for India in Council.) Birds. Vol. 3. Second edition. By E. C. Stuart Baker. Pp. xx + 489 + 7 plates. (London: Taylor and Francis, 1926.) 30*s*. net.

WITH the publication of this volume, which, like its two predecessors, deals solely with the Passeres, the author has brought to a conclusion his work on that great order of birds. In the three volumes issued up to date, 1336 species and subspecies have been recognised. In the first edition of the Avifauna, the Passeres were dealt with in two volumes, and the number of species then acknowledged was 936. The advance of ornithology has therefore given Mr. Stuart Baker much more ground to cover, largely owing to the necessity for his dealing with the numerous racial forms which have of late years been described.

The high standard set in the first two volumes has been fully maintained in the present one, which, in addition to numerous woodcuts, contains seven coloured plates by the author, that of the Zosterops being particularly pleasing.

The map of India which accompanies the volume would have been more instructive had the topographical features of the country been more clearly shown. The account of the birds of British India will probably be completed in three additional volumes.

The Statesman's Year Book: Statistical and Historical Annual of the States of the World for the Year 1926. Edited by Sir John Scott Keltie and Dr. M. Epstein. Sixty-third Annual Publication, revised after Official Returns. Pp. xxxvi + 1496. (London: Macmillan and Co., Ltd., 1926.) 20*s*. net.

EACH issue of this work of reference adds new features without sacrificing the old. The arrangement of countries remains the same, except that the kingdom of Hejaz has lost its place among the independent states. It is in regard to India that the principal changes occur. That section of the book has been expanded from forty-four to sixty pages, the increased space being devoted to the provinces of British India and the independent states over which the Indian Government exercises certain control. Each of these entities is now treated in the same way as the provinces of other parts of the Empire. Among the introductory matter, which includes a section on the League of Nations, new features are sections on the International Institute of Agriculture, a list of European and North African air routes, and tables showing taxation, national debt charges, and paper currency of various countries. The coloured maps are two, showing the distribution of republics and other political divisions in the Soviet areas in Europe and Asia. In spite of additions the bulk of the volume is not increased.

A Report on the Sugar Cane Mosaic Situation in February, 1924, at Soledad, Cuba. By Prof. Edward M. East and Prof. William H. Weston, Jr. (Contributions from the Harvard Institute for Tropical Biology and Medicine, 1.) Pp. vi + 52 + 9 plates. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1925.) 8*s*. 6*d*. net.

IN this, the first of a new series of publications from Harvard University devoted to tropical biology and medicine, an account is given of the mosaic disease of sugar-cane as seen by the authors on the Soledad estate, Cuba. The disease is thought to be of long standing in Cuba (unlike most of the British West Indies), but, at Soledad, it is not appreciably reducing the yield and quality of the Crystalina cane ordinarily grown in the island. The extensive bibliography, and the plates (some in colour) showing mosaic and certain other types of chlorosis in sugar-cane and maize, are useful features of the book.

Geography in School. By James Fairgrieve. Pp. x + 364. (London: University of London Press, Ltd., 1926.) 7*s*. 6*d*. net.

THERE is little that is new in this book, but there is nothing that is not said in an interesting way. Every thoughtful teacher of geography has faced the problems which the author discusses in the light of his long experience of school work, and no teacher could fail to derive something of value from what Mr. Fairgrieve has to say. Especially valuable is his insistence on reality in geography and his warnings of misunderstandings that are liable to be caused by the necessarily small scale of so many maps and the lack of personal knowledge of the world of most teachers. The book has a useful bibliography and full index.

Pression de la lumière. Par Pierre Lebedef. Traduit du russe par T. Kousmine. (Collection de monographies scientifiques étrangères, No. 9.) Pp. 71. (Paris: Albert Blanchard, 1926.) 7·50 francs.

PIERRE LEBEDEF devoted twelve years of his life to the study of the pressure of light, and this little monograph gives us, in a convenient form, a description of his experiments. The work practically consists of two papers, one on the pressure exerted by light on solids, and the other on the pressure on gases, the latter being important because of its application to the tails of comets. Some bibliographical notes are appended.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Muscular Action.

A NUMBER of papers by various writers have recently appeared on this subject, mostly dealing not with the action of the muscle itself but with the material consumed by its action and the products formed by their consumption. Taking the somewhat parallel case of an engine, the papers alluded to aim at describing what is put into the fire-box, what falls into the ash-pan, and what goes up the chimney. Nothing of any value, however, is said as to the nature of the engine, its efficiency, or how and why it performs its work. The function of a muscle is to exert a pull, and the pull depends on the shortening, or tendency to shorten, of the cells of which the muscular fibres are composed, when something is transmitted to them by the nerves.

One would like to know—What is it that the nerves transmit? And what is the origin and nature of the force which deforms or tends to deform and shorten the cells?

A nerve can be made to act on a muscle in many ways; by electric currents, for example, or by chemical or mechanical irritation, but this does not indicate the character of the natural stimulus any more than the fact that a pipe can convey power to an engine by carrying water or gas indicates the real nature of its contents.

Nervous stimulus involves the expenditure of work independently of the work done by the muscle in which it induces contraction. What is the proportion between these two expenditures? Again, as regards efficiency. Efficiency may be specified either as the over-all efficiency, by comparing the potential work in the fuel with that realised by the engine, or, what is more important as regards muscular action, by the work expended in the muscle compared with the realised external work.

When a muscle is in tension, work is expended whether the muscle remains stationary or contracts; but it is only during contraction that useful work is done, and the work consumed in keeping a muscle taut but stationary amounts to a leakage of power.

Does this leakage continue at the same rate for the same tension while the contraction is going on?

This might well form the subject of experiment, and were it determined it would be possible, for any particular case, to state the most efficient speed of contraction.

So far as is known, all the work done by the muscles in accelerating themselves and their attachments is wasted. In walking on a resilient level surface, for example, the whole of the muscular work is spent in this way, for the walker might perform the same journey in a frictionless carriage by merely starting it with a push the energy of which could be recovered at the journey's end.

It must not be assumed, however, that the whole of the acceleration of the leg in walking is supplied by muscular effort. The legs, like pendulums, have natural periods, and the muscular acceleration is that required to convert the natural period of the leg to the forced period of the step.

Letters touching on these questions have already been published in NATURE of April 15, 1920; June 3, 1922; and January 31, 1925.

A. MALLOCK.
9 Baring Crescent, Exeter, June 19.

Collisions of the Second Kind with Excited Mercury Atoms in the 2P State.

A NUMBER of experiments have recently been performed by various experimenters in which a mixture of gases containing mercury vapour as one constituent has been illuminated by light from a water-cooled quartz mercury arc. In interpreting the results of these experiments it has generally been assumed that the following process takes place. Mercury atoms first absorb radiation λ2536, an electron thereby being raised to the $2p_2$ state. Having reached this excited state the mercury atom may collide with one of the other atoms or molecules present and transfer its potential energy over to the other atom or molecule. The energy thus transferred may do one of several things. It may cause a molecule to dissociate; it may excite the colliding molecule or atom; it may all be changed into thermal kinetic energy of the two colliding bodies; or it may do combinations of the above.

In the interpretation of their results most of the experimenters have considered only the effect of mercury atoms in the $2p_2$ state. Recent experiments performed by the writer have shown that mercury atoms in the $2P$ state are also effective in the above process.

The apparatus and method were the same as used by Loria (*Phys. Rev.*, **26**, 573-584, Nov. 1925) with his sealed-off tubes. A mixture of zinc and mercury vapours was illuminated by the light from a water-cooled quartz mercury arc, and the following zinc lines were observed.

Wave length (Å U.)	Intensity	Notation.	Energy necessary to excite (volts)	Remarks
4810 4722 4680	8	$2p_{1,2,3}-1s$	6·63	Sharp triplet
3345? 3302 3282	2	$2p_{1,2,3}-3d$	8·48	Diffuse triplet
3075	5	$1S-2p$	4·01	Resonance line
2138	2	$1S-2P$	5·77	,, ,,

λ3345 is hidden by the mercury line λ3341. λ2138 was only obtained with long exposures.

When the exciting light was filtered through weak acetic acid (concentration 1 in 180) the zinc sharp triplet was reduced to an intensity of 2 λ2138 did not appear, but the exposure was not long enough to show definitely anything about this line. The intensities of the other lines remained very nearly the same. This weak acetic acid was found to absorb completely all wave-lengths shorter than λ2000 and to transmit λ2536 with nearly full intensity

When this mixture of zinc and mercury vapours was illuminated by the uncooled or hot mercury arc, the sharp triplet and a very faint trace of λ2138 appeared. The zinc diffuse triplet and the resonance line λ3075, if they appeared at all, did not have sufficient intensity to be seen on the plate. When the exciting light was filtered through weak acetic acid no zinc lines appeared.

These results may be interpreted as follows. When the mixture of zinc and mercury atoms is illuminated by light from the water-cooled mercury arc, some normal mercury atoms are raised to excited states by absorbing light. Some of them absorb λ2536, an electron thereby being sent to the $2p_2$ level. In this state the atom has a potential energy of 4·86 volts. Other mercury atoms absorb λ1849, an electron going

to the $2P$ level, giving these atoms a potential energy of 6·67 volts. Now, excited mercury atoms of either kind may collide with normal zinc atoms and transfer their potential energy to the zinc atoms, which are thereby raised to excited states. If an excited mercury atom has more energy than is necessary to excite a zinc atom, the energy remaining changes into thermal kinetic energy of the two colliding atoms. The excited zinc atoms returning to the normal state give out the zinc spectrum lines observed.

The energies necessary to excite these observed zinc lines are given in the table above. The only zinc line which a $2p_2$ mercury atom with its 4·86 volts energy could excite is λ3075, requiring 4·01 volts. A $2P$ mercury atom having an energy of 6·67 volts might excite either the sharp triplet requiring 6·63 volts or λ2138 requiring 5·77 volts. When we filter the exciting light through acetic acid, λ1849 is absorbed but λ2536 is transmitted. This means that no mercury atoms can now be raised to the $2P$ state, but about the same number can absorb λ2536 and reach the $2p_2$ state. As a result the intensity of the sharp triplet is much reduced, showing that it owed most of its existence to $2P$ mercury atoms. The zinc line λ3075 kept nearly the same intensity, showing that it depended principally on $2p_2$ mercury atoms.

When we illuminate by the hot arc, in which λ2536 is reversed, no mercury atoms will absorb λ2536 and be changed to the $2p_2$ state. However, we have some mercury atoms in the $2P$ state which have absorbed λ1849, and these collide with zinc atoms, causing them to emit the sharp triplet and λ2138. Now if we filter the light from the hot arc through acetic acid, λ1849 is absorbed and we have no excited mercury atoms present. Consequently no zinc lines appear.

There is some evidence that the zinc diffuse triplet requiring 8·48 volts is caused by mercury atoms in the $3d$ state. The discussion of this triplet will be reserved for the full report of this work.

It might be said that the zinc atoms could absorb λ1849 directly without the necessity of the intermediate $2P$ state of mercury. Powers (*Phys. Rev.*, **26**, 761-765, 1925) and Kapuscinski (NATURE, 116, 170 and 863, 1925) have found such a possible absorption for cadmium. In order to test this possibility, these experiments were repeated with a tube containing pure zinc and practically no mercury vapour. No zinc lines were obtained in any case.

These experiments show, then, that the effect of mercury atoms in the $2P$ state must be considered in the interpretation of the results obtained when any mixture of gases including mercury vapour is illuminated by a quartz mercury arc.

Madison, Wis., U.S.A., May 24.

Activated Fluorescence and Doppler Effect.

KLEIN and Rosseland deduced from thermodynamical considerations that an excited atom can, in consequence of a collision, fall into the normal state without emission of radiation (impact of the second kind). A part of the energy that becomes free can be spent in exciting the other atom, giving rise to the phenomenon of the "activated fluorescence" which was found to occur in mixtures of metallic vapours by Franck and his school.

For example, if mercury atoms which are brought into the $2p_2$ state by absorption of the 2537 line (corresponding to a potential of 4·9 volts) collide with atoms of another element possessing a lower resonance potential, the lines of this element are found to be emitted. The excess of energy must be distributed between the two atoms as kinetic energy.

As no direct proof of this latter point, so far as I know, has been given, I have tried to observe the speed acquired by the atoms as a Doppler effect, and I give here a preliminary account of the results, which agree also quantitatively with the theory.

I used a mixture of mercury and sodium vapours, contained in a bulb of fused silica, which was continuously evacuated by a diffusion pump. The mercury was put into a side tube, heated to 120°, so that the pressure of its vapour in the bulb was of the order of 0·5 mm. The bulb contained some sodium, and was heated to 300°-350°. On illuminating with the light of a water-cooled mercury lamp, a visible glow of D light appeared. The D lines were observed with a 40-plate echelon grating, and their breadth was measured with an ocular micrometer. It was found to be, as a mean value of six observations on D_1 and D_2, 0·16 Å.U. The lines were strongly reversed, the central part being absorbed by the sodium vapour before escaping from the bulb.

The breadth to be expected is easy to calculate. The kinetic energy must correspond to the difference $V_2 - V_1$ of the excitation potentials of mercury and sodium, *i.e.* to 4·9 − 2·1 = 2·8 volts; hence, and from the law of the conservation of momentum, we get the equations—

$$m_1v_1 = m_2v_2\ ;\quad \frac{m_1v_1^2 + m_2v_2^2}{2} = e(V_2 - V_1),$$

where m_1, v_1 and m_2, v_2 are the respective masses and velocities of the two atoms. The velocity of the sodium atom (which owing to its smaller mass absorbs nearly all the energy) is thus found to be $4{\cdot}3 \times 10^5$. The distribution of the velocities of the excited sodium atoms is uniform as regards the direction in space, but is not a Maxwellian distribution, because the molecules have all the same velocity. Hence it follows that the distribution of the intensity in the broadened line is quite different from that due to the ordinary Doppler effect of thermal agitation; and it is easy to see that our distribution must be a uniform one, with a breadth of the lines $\Delta\lambda = 2\lambda v/c$. Introducing for v the value given above, we obtain $\Delta\lambda = 0{\cdot}17$ Å.U., which agrees with the observed results within the limits of experimental error.

Also the distribution of intensity, so far as could be determined by eye observations, agreed completely with that predicted by the theory. To be sure that the broadening of the lines was due to the expected effect, I observed with the echelon spectroscope the D lines obtained by resonance in a bulb at the same temperature as in the previous research, illuminated with the light of a sodium vacuum lamp; the lines were found to be very narrow.

FRANCO RASETTI.

High Frequency or Ironless Induction Furnaces.

IN an unsigned article in NATURE for May 29, entitled "High Frequency or Ironless Induction Furnaces," the writer suggests that his experiments on the heating of copper cylinders under certain conditions are at variance with the conclusions reached in our paper on this subject.

The statement in question was, ". . . consider the frequency which gives maximal (misquoted as "maximum") heating in several cases." Maximal in respect to what? Constant voltage applied to the inductor (!) or constant inductor current? (as the writer seems

to imply). He should have appreciated that neither condition was assumed.

We were considering maximal charge heating under constant power input to the inductor, and it was expressly stated that only inductors satisfying certain conditions were contemplated. The writer's experiments have no relation to the statement in question. Let us examine his experiments more closely.

We believe that the Ajax-Northrup inductor has 1·6 turns/cm.; then with 200 amp. at 50 cycles, a long cylinder of copper 5 cm. in diameter would absorb approximately 3 watts per cm. length. An elementary calculation indicates that this power would result in a temperature rise of 13° C. in 5 minutes—a temperature rise which might well escape the notice of hand-thermometry.

On the other hand, at 25,000 cycles, the power input would be 67 watts per cm. length into cold copper, and this, when account is taken of the large temperature coefficient of resistivity of copper, would in 8 minutes result in a temperature approaching 700° C.

It is important to remember that the resistivity of copper at its melting point is nearly six times its value at room temperature, so that the lowest frequency at which copper could be efficiently melted in 5 cm. diameter cylinders is about 220 cycles per second.

The fact that the charge has finite length will tend to increase the heating at the higher frequencies, and when it is borne in mind that the Ajax-Northrup converter produces damped waves ("containing all frequencies"), it will be realised that no very great precision can be claimed for these calculations. They are, however, more definite than the writer's statement of his inductor current—a statement more likely to satisfy the potential user than the physicist.

Again, regarding the exception which we have taken to Northrup's "fundamental statement" that at high frequency "the resistance of a charge is equal to its reactance," surely it is about time that this remark, which has appeared in technical papers for the last ten years, was laid to rest. Scientifically it is wrong; commercially it does not appear to serve any useful purpose, and even at the risk of being "noteworthy" we must continue to take exception to a "fundamental statement" by any authority when it is fundamentally incorrect. We must repeat that the ratio of resistance to reactance at high frequency is

$$\frac{1}{\sqrt{2\pi}\,.\,R}\sqrt{\frac{\rho}{p}}.$$

N. RYLAND DAVIS.
C. R. BURCH.

Research Department,
Metropolitan-Vickers Electrical Co., Ltd.,
Trafford Park, Manchester, June 3.

IN reply to the communication of Messrs. Burch and Davis, I have to say that:

1. The anonymity of the article was not of my seeking. My name was omitted owing to a misunderstanding.

2. I regret misquoting maximal as maximum. The use of the English equivalent did not, however, alter the meaning of the quotation.

3. The last paragraph of their letter evidently arises from some misinterpretation. In my article I pointed out quite legitimately that they took exception to a certain statement of Northrup's but made no comment, favourable or otherwise, concerning their attitude.

4. Implied criticisms concerning the accuracy of my measurements are out of place, since the experiments were intended to show, and did show clearly, that under practical conditions and at frequencies specified by the authors the heating effect on the copper charge was not merely less than some other value, but insignificant.

5. The authors state that only inductors satisfying certain conditions were specified. As it is impossible to construct inductors exactly complying with the theoretical conditions, their arguments are out of reach of rigid experimental verification. On the other hand, they arrive at certain general conclusions from which it can be deduced that an inductor current of, say, 25-50 cycles frequency would be suitable for heating a cold copper charge of 3 cm. radius. I endeavoured to check this conclusion experimentally at 50 cycles, and although a kilowatt was being dissipated in the inductor coil, no serious temperature rise of the charge took place in a period of 5 minutes. The inductor coil was designed for high frequency currents, and from this point of view the conditions were not favourable for the low frequency experiment.

The conclusions of Burch and Davis are so revolutionary, and if capable of practical application are so important, that I hope shortly to repeat the experiment, using an inductor specially designed for low frequencies. Such an experiment should determine if ironless inductive heating at these low frequencies is a practical proposition.

FRANK ADCOCK.

The Drop-weight Method of Measuring Surface Tension.

THE letter by Prof. Harkins on the above subject in NATURE of May 15 seemed to me to be very interesting. As, however, he has severely criticised my own views on the subject, I have thought it best to make some reply, for it is possible that a misunderstanding has arisen.

The method I adopted for calculating surface tension from the weights of drops of liquid falling from circular tubes is given in the *Philosophical Magazine*, vol. 45, p. 1088, 1923. I would refer any one interested to this paper, as it is quite unnecessary to reproduce any of the details here. The method was based on certain postulates which might replace Tate's laws in the greater accuracy with which they expressed the experimental facts, and which also seemed to lend a certain clarifying expression to the hopeless rigmarole that has been written round the subject for so many years. The fundamental operation in my calculations is certainly *not* taken from Harkins's work. I used certain data of Harkins and Brown (*Jour. Amer. Chem. Soc.*, vol. 41, p. 512, 1919), because at the time they were the most accurate I could find, and I saw no reason for repeating the experimental work unless I could be reasonably sure of a greater accuracy.

Harkins refers to my method as "cumbersome," "indirect," "involved," etc. The calculations could easily be shortened by the compilation of certain tables, but I do not understand why the ordinary mathematical operations of addition and multiplication should be "cumbersome" in my case and not in Prof. Harkins's. I suppose my method may be considered indirect because I have not followed in the tradition of certain formulation from which to the more conventional-minded it would be wrong to depart.

In ignoring the difference in gravity for Chicago and London, I have incurred an error in my results of 1 in 1000. It will be seen from my paper that I have merely given the figures for the surface tension correct to about 1 in 450.

Harkins's ingenious attempt to show that a drop hanging from a circular tube must inevitably satisfy

the equation $W = 2\pi r\gamma$ when the radius of the tube becomes extremely small, is not by any means conclusive, and does not seem to be supported by adequate experimental evidence. In any case, it could only be proved by extrapolation from a curve, and we should find ourselves involved in an argument as to whether the surface tension is the same for a thin mass as for the bulk of the liquid in all cases. The truth is that neither Harkins nor any one else has ever given a quite satisfactory solution of the dynamical problem of the drop detachment. His way out of the difficulty seemed to me to be somewhat vague and unsatisfactory; but that is only a point of view, and perhaps may not matter very much.

The main point at issue seems to be whether it is worth while checking any further propaganda on behalf of my method as opposed to Prof. Harkins's; and on this matter, of course, I have nothing to say. But I should be glad if Prof. Harkins would point out where my method is "erroneous," as at the moment I do not know what to make of his extremely general criticism, which occupies nearly two columns of this journal, and to which I can only make an equally indefinite reply. T. IREDALE.

Cirrus at a Lower Level than Alto-cumulus.

IN his letter to NATURE of February 6, 1926, p. 199, Mr. C. J. P. Cave has directed attention to the fact that well-defined cirrus clouds may occur at a much lower level than we generally assume to them, say, under a sheet of alto-cumulus. To support his view he describes a striking observation similar to that made by me on Sunday, June 13, at Strasbourg. During the morning and early afternoon of that day the weather was rainy and the sky covered with alto-stratus and nimbus. The nimbus ceased about 16.30 (G.M.T.) and the alto-stratus merged gradually into a sheet of fleecy alto-cumulus moving from west-south-west. It had a straight edge separating it from a beautiful clear sky.

At 17.30 I saw at an angular altitude of near 45° to the east-north-east a patch of well-defined white cirrus clouds under the alto-cumulus, and detached from them. As at the same moment many cirriform streaks were developing from alto-cumulus and acquiring the form of *cirrus-uncinus*, I believe the cirrus mentioned above may have been similar streaks afterwards separated from alto-cumulus.

Later, in the clear blue sky, some of these streaks were seen that had lost their *cirrus-uncinus* form. I am sure that if any one had observed the sky only at this moment he would undoubtedly have noted common cirrus, and there is no reason, I suppose, to say that they have not the same structure, as we know that in many cases high cirrus clouds are formed by snowflakes.

It is interesting to note that Mr Cave's observation and my own were made exactly with the same sky aspect; namely, a sheet of alto-cumulus with a straight edge and cirrus seen under it, near the edge. We are thus led to ask: Is all the low cirrus derived from alto-cumulus, and is it always seen near the edge of the sheet? The cirrus derived from the anvils of cumulo-nimbus seems to be an exception. The general meteorological conditions of the days of the two observations as regards cloudiness were also similar, the clouds being placed at the transition of a "corps" to a "traîne" of a "cloud system," using the modern French nomenclature. On January 24 a low pressure area was above western Scandinavia and another to the south-west of Iceland. These were fast-moving depressions with well-defined warm sectors passing over the British Isles. On June 13 a low-pressure area was situated to the west of Ireland, and it commanded in Europe a circular occlusions.

A revision is desirable of the altitudes assigned by the International Classification to the cloud forms, and also of the definitions of these forms, to take into account the new ideas of the structure and formation of clouds. ANTONIO GIAO.

The Zoological Names *Simia*, *S. satyrus*, and *Pithecus*, and their Possible Suppression.

THE attention of the zoological profession is invited to the fact that the proposition is before the International Commission on Zoological Nomenclature to re-open the case of *Simia*. In its present form the proposition is for the Commission: (*a*) absolutely to suppress the generic names *Simia* and *Pithecus* and the specific name *Simia satyrus*, on the ground that retention of these names and the application of the rules to them will produce greater confusion than uniformity; (*b*) to insert into the Official List of Generic Names, *Chimpansee* Voigt, 1831, 76, for the chimpanzees *Pongo* Lacépède, 1799, type *pygmaeus* 1760, for the orang-utans, and *Macaca* Lacépède, 1799, type *sylvana* 1758, for the Barbary ape.

The argument before the Commission gives an extensive historical review of the subject; this will be published in Bulletin 145, Hygienic Laboratory.

Briefly summarised, the argument maintains: (1) that because of the importance of the Primates in connexion with investigations on infectious diseases, the nomenclature of certain genera has passed far beyond a status in which this subject is of importance only to zoologists in general and to mammalogists in particular; (2) that it is absolutely essential that unambiguous names be adopted internationally for experimental animals used for studies dealing with problems involving the life and death of human beings; (3) that the names *Simia*, *Simia satyrus*, and *Pithecus* are so confused in zoological literature as to preclude hope of reasonable uniformity in their use in zoological, bacteriological, serological, and public health work; (4) that the safest solution is to suppress these names entirely; (5) and that the International Commission should select thoroughly unambiguous and suitable substitutes which will preclude possibility of confusion in interpreting results as reported by bacteriologists and others in different countries—results which deal with human life.

The secretary will delay announcement of final vote until about September 1, 1927, in order to give to zoologists, bacteriologists, and others who may be interested, time to consult the premises formulated in Bulletin 145, and to express their views to the Commission. Application for copies of Bulletin 145, Hygienic Laboratory, should be addressed to the Surgeon-General, U.S. Public Health Service, Washington, D.C. C. W. STILES,
Secretary to Commission.

Hygienic Laboratory, Washington, D.C.

Names for Companion Stars.

I HAVE been expecting to see some comment in NATURE upon Sir Oliver Lodge's suggestion under the above title in the issue of March 13, 1926, but none seems to have appeared. It is not my purpose to dwell upon the propriety of naming so insignificant and dense an object as the companion to Sirius for

one whose contributions to science have been so large and brilliant. It is the suggestion regarding the companion to Algol that needs comment. Vogel's contributions to the art of measuring radial velocities put him in the first rank, but they do not include the discovery of the first spectroscopic binary. As this is an error that has often been repeated it may be well to set down the facts.

In his third annual report on the Henry Draper Memorial, published early in 1889 (our copy reached New Haven on April 16), E. C. Pickering states: "One photograph of Zeta Ursæ Majoris shows the K line distinctly double, and others show it single." In the January, 1890, number of the *American Journal of Science*, Pickering has an article dated November 12, 1889, in which he states that the K line in this star occasionally appears double, and he goes on to give what we now know to be the correct explanation, namely, that we are dealing with a binary, both components of which are bright.

At the meeting of the Prussian Academy of Science held on November 28, 1889, Vogel communicated six observations of Algol which show it to be a spectroscopic binary. These observations were first printed in *Astronomische Nachrichten* 2947 (dated January 11, 1890), in an article by Vogel dated December, 1889. Vogel's first observation of this object is dated December 4, 1888, while the duplicity of the lines in the spectrum of Zeta Ursæ Majoris was noted on a plate secured at Harvard on March 29, 1887. We see, therefore, that no matter what criterion is used to fix the epoch of the discovery of the first spectroscopic binary, we must conclude that the first of these objects to be detected was Zeta Ursæ Majoris by Pickering.

The above illustrates a difficulty which will be constantly met if Sir Oliver's suggestion is followed out; we should often be involved in matters of priority if these names are assigned during the lifetimes of the investigators concerned or too soon after their deaths.

Energy Levels of the Carbon Monoxide Molecule.

IN their communication under this title in NATURE of July 3, p. 12, Messrs. Duffendack and Fox make a suggestion in connexion with the scheme of electronic energy levels of neutral carbon monoxide which I recorded in a recent letter. It is briefly, that there are two sets of levels involved corresponding to triplet and singlet terms in the corresponding atom. I would like to say that this and other suggestions were made to me by Prof Birge and Dr. Mulliken in private communications some three months ago, but too late for publication in my letter. It is clear that the whole scheme of levels can be interpreted on Birge's views, which are outlined in his important letter on "The Structure of Molecules" (NATURE, Feb. 27, 1926). The common ground level is $1S$. The initial levels of the 4th positive and the Ångström bands are respectively $1P$ and $2S$. The initial level of the Cameron bands is the triplet $1p_{123}$, and of the third positive bands is $1s$, while the new level which Duffendack and Fox postulate is probably $2p_{123}$. All the above levels have their counterpart in the corresponding magnesium atom, and the inferences which may be drawn therefrom account for all the facts.

The $3A$ positive bands of Duffendack and Fox are clearly the bands which I interpreted as an $n'=4$ sequence. The interpretation as arising from a $2p_{123}$ level is, however, preferable for two reasons: it avoids the anomalous intensity distribution in which the states $n'=2$ and 3 are absent, and secondly, the existence only of the states $n'=0$ and 1 is in harmony with recent work of Birge and Sponer on the heat of dissociation of the molecule. It may perhaps be added that not only are s to s transitions possible in band spectra but so also are p to p transitions (*e.g.* the $3A$ bands of carbon monoxide).

The Physical Basis of Insect Drift.

THE letter of Dr. E. P. Felt (NATURE, May 29, p. 755) illustrates how difficult it is in these days for the student of one science to keep in touch with developments in other sciences, developments which may have a considerable bearing on his own subject. We know all too little about the conditions in the upper air, but we know more than "the extremely few observations made by airmen in balloons, dirigibles, or aeroplanes." If Dr. Felt were to get in touch with the Weather Bureau at Washington, or with the Blue Hill Observatory, he would probably be able to obtain data which would be of great value in connexion with the question of insect drift. Observations of wind in the upper air are made as a matter of routine in many places in the northern hemisphere, and in some in the southern, so that there should be plenty of material to work on.

No doubt winds in the upper air have a great deal to do with the dispersal of insects, and convection currents occur at times up to much greater heights than those mentioned by Dr. Felt. At the same time there may be other factors besides wind; it is not easy to see how the extraordinary migrations of *Vanessa cardui* in Europe can be explained on purely meteorological lines unless other insects are similarly affected, which, so far as I know, is not the case. No doubt the appearance of *Colias edusa* in England from time to time might be explained by meteorological considerations, but if so a "clouded yellow year" should be a year when other continental forms appear here There is evidently scope for a considerable amount of team work between meteorologists and entomologists.

Abnormal Venous Circulation in a Frog.

ONE of our senior boys here, Alan Cadbury, when dissecting a frog, directed my attention to the fact that the right anterior vena cava appeared to be completely missing. Closer examination proved this to be actually the case In order to return the blood from the right anterior region of the body to the heart, a commissural vessel had been established connecting the bases of the external jugular vein of the two sides, the venous blood from the entire anterior region of the body thus finding its way back to the sinus venosus through the left anterior vena cava. The specimen was a well-grown male.

In a communication to NATURE of April 25, 1925, Dr. N. B. Eales has directed attention to variations occurring in the distribution of the anterior abdominal vein of the frog and remarked on their evolutional significance. No such significance can be plausibly attached to the present case, but the anomaly seems rare enough to be worth recording. The anterior abdominal vein opened into the liver as usual.

Oxidation, Passivity, and Corrosion.[1]

By ULICK R. EVANS.

WHEN a clean surface of metal is heated gently in air, a fine series of colours is often produced, the sequence of tints being that which would be expected from optical principles. In the case of lead, four 'orders' of tints can be observed: red, for example, occurs four times in the sequence. The transparent oxide film which is responsible for the effect can be lifted from the lead, and it is found that for any given film the colour as seen by reflected light is complementary to that seen by transmitted light. On copper and iron the sequence is essentially the same as on lead, but the fourth-order tints (corresponding to fairly thick films) cannot be seen; indeed on iron—no doubt owing to the low transparency of the oxide—only the first-order colours are really bright, although, if the oxidation is carefully carried out, the sequence can easily be followed as far as the third-order red.

It is important to notice that absolutely no change in the appearance of the iron occurs until the first yellow 'temper tint' arrives; this appears quickly at high temperatures, more slowly at lower temperatures. At ordinary temperatures iron can be kept in dry air indefinitely without undergoing visible change. It is generally considered that an oxide film is produced; but that, since diffusion of oxygen through an oxide is very slow at low temperatures, the film becomes protective, and ceases to thicken further, before it reaches the thickness needed to give the first (yellow) temper colour.

This view is supported by some experiments on the changes produced by oxygen on the chemical behaviour of electrolytic iron. The iron was very kindly prepared for me by Dr. W. H. Hatfield; it was fused *in vacuo* in a magnesia crucible before being rolled into sheet. When freshly ground, the iron was found to be capable of precipitating copper from $N/10$ copper nitrate solution within a few seconds. But after exposure for 21 hours to dry air or oxygen (freed from carbon dioxide) it was found to lose its activity, and drops of the copper nitrate solution then produced no effect even after standing on the surface for many hours. In other experiments, strips of the iron, freshly ground, were subjected to a temperature gradient in air or oxygen, so as to give a film of gradually increasing thickness, ranging at one end from thicknesses too small to give temper colours, through intermediate thicknesses displaying the three orders of tints, up to considerable thicknesses at the other end, where the scale had the slaty-grey appearance characteristic of magnetite.

On testing the films with small drops of copper nitrate, it was found that only a limited range of thicknesses afforded protection; this range was situated in the invisible region, and extended almost—but not quite—to the place where the first yellow tint commenced. At points near to the unheated end of the specimen, where the film was too thin to give protection, general deposition of copper quickly occurred. Near the heated end where the film was visible the protection also failed, but in a different way. Deposition of copper commenced at certain isolated points or lines, and spread out from these places over the oxidised surface. This copper was certainly deposited on the *outside* of the oxide film, since when the copper was afterwards dissolved away with ammonia the oxide film reappeared. The points around which deposition occurred almost certainly represented pores or cracks in the oxide scale; indeed, in the thicker scale, the cracks were sometimes visible. At a crack, the exposed iron would act as the anode of a local cell and the oxide around as cathode, copper being deposited on the latter without destroying it.

The behaviour of the part of the strips showing temper colours is of some interest. A short immersion in copper nitrate solution causes the tints to become dull, owing to the deposition of metallic copper upon the film (the colour of this copper can be seen if the specimen is held at a suitable angle); at the same time, the tints shift in a direction which would seem to indicate a thickening of the film at each point. If, at this stage, the copper is dissolved away with ammonia, the colours re-emerge with practically undiminished brightness. If, on the other hand, the strip is kept in the copper nitrate solution until the colours are completely hidden by a thick deposit of pink copper, the colours, when the copper is dissolved away by ammonia, reappear distinctly weaker than before.

Analogous results are obtained when copper strips, covered with an oxide-film of varying thickness, are treated with dilute silver nitrate, although on copper the protective power of an oxide skin is much less permanent than in the case of iron. The maximum resistance is again situated in the invisible region, but the films thick enough to give first-order tints resist the reagent for almost as long a time. As in the case of iron, the thick films fail in quite a different manner from the very thin films; on the thick films tiny isolated crystals of shining silver appear, no doubt at the sites of pores, whilst where the film is very thin general deposition of darker silver occurs.

Both on iron and copper the behaviour of the oxide-film in protecting the metal varies *gradually* as the thickness is increased: there is no sharp change at the point where the first visible tint appears. This observation has a bearing on the cause of the 'passivity' displayed by iron which has been treated with oxidising agents. Some authorities have maintained that this cannot be due to a protective film, basing their argument on the facts (1) that no film is visible on passive iron, and (2) that iron covered with a visible film is not, as a rule, passive. These particular objections to the oxide film theory would seem to possess but little weight. The poor protection afforded by relatively thick visible films is almost certainly due to the increase in the probability of spontaneous cracking which accompanies an increase in thickness. Clearly, however, the conditions of formation of the film greatly affect the protective character; some oxidising agents, for example, seem to give more reliable films than oxygen itself. It is, of course, possible that other causes besides the presence of a film on the iron might

[1] Based on two lectures on the "Tinting, Tarnishing, and Corrosion of Metals," delivered at the Royal Institution on May 20 and 27.

give rise to the phenomenon known as passivity; but all the cases so far examined by the present writer appear to be due to protective films.

It is well known that solutions of oxidising agents, such as chromates, render iron passive towards copper salts. In the case of electrolytic iron this passivity can also be brought about by dissolved oxygen, provided that it is present in sufficient quantity at all points on the surface. Since oxygen is not very soluble in water, some special arrangement is needed to ensure the oxygen supply to the point where the specimen is supported. This can be attained by using the "eccentric whirler" recently described by the writer [2]; the specimen, consisting of a metal disc pierced centrally with a circular hole, is slipped over a glass tube blown to bulb-form at the lower end, and attached eccentrically on a vertical spindle, which can be driven by a motor. When the spindle rotates, the whirling disc mounts the tube and the point of contact with the glass alters from one moment to the next; thus there is no fear of oxygen exhaustion at the point of support. If a disc of mild steel is thus 'whirled' in distilled water containing oxygen, it soon attains a yellow appearance, due to the formation of adherent ferric hydroxide over the surface generally; [3] if taken out after 100 minutes, dried and tested with copper nitrate, the iron is found to blacken within a few seconds. When, however, the experiment is repeated with electrolytic iron, quite different results are obtained. It is found that this material develops rust only in minute spots, between which the metal remains bright; the spots probably represents the sites of pores in the metal into which oxygen cannot rapidly penetrate; only a trace of iron passes into solution. If the specimen is taken out after 100 minutes 'whirling,' the iron is found to be quite passive towards copper nitrate. Some specimens of electrolytic iron have been found to remain free from rust altogether when whirled for many hours in water containing oxygen, probably because they were free from pores.

It should be understood that the comparatively non-rusting behaviour of electrolytic iron only refers to conditions of *uniform aeration*. If the same iron is exposed in the same water under conditions of *differential aeration*, rusting occurs readily. Thus if a strip of electrolytic iron be partly immersed in a nearly vertical position in the water, so that oxygen reaches the upper part more easily than the lower part, corrosion quickly commences; it is plainly visible after 30 minutes. Iron passes into solution at the points where the oxygen-concentration is lowest as the comparatively soluble ferrous hydroxide, and although this will ultimately be oxidised to the much less soluble ferric hydroxide (the main component of 'rust'), the ferric hydroxide, being formed as a secondary product at an appreciable distance from the seat of origin of the ferrous hydroxide, does not form a continuous film over the metal and has no protective character.

The setting up of corrosion by differential aeration is well shown by experiments on the behaviour of steel in contact with sodium chloride solution. When a drop of salt-water is placed on a sheet of mild steel, corrosion occurs in the centre of the drop; the peripheral portion of the drop—the part which oxygen can reach most readily—remains quite uncorroded. Similarly, if a strip of steel be partly immersed in sodium chloride solution, corrosion occurs over the portions well below the surface; just below the water-line there is a zone of quite uncorroded metal.

Experiments have shown that the corrosion is connected with electrical currents set up by the variation in oxygen concentration; the portion where the oxygen concentration is lowest functions as the anode, or corrodible portion. These currents only flow if oxygen is supplied continuously to the cathodic area, but they produce corrosion upon the part which is not directly reached by the oxygen. The mechanism would appear to be as follows. Oxygen reaches the portion next to the water-line and causes a kind of passivity. The potential is raised above that of the lower, relatively unaerated, portions, and this determines the flow of current; measurements by McAulay and Bowden [4] have shown that the potential over the aerated zone may become so much as 0·2 volt 'nobler' than that of the unaerated zone. The unaerated portion suffers anodic corrosion yielding ferrous chloride, whilst at the aerated portion the cathodic reaction produces sodium hydroxide; along the line where the ferrous chloride and sodium hydroxide meet, we get white ferrous hydroxide, rapidly oxidising through the green intermediate body, to brown ferric hydroxide, and thus a membrane of rust is produced at the junction of the anodic and cathodic regions. Thus the *direct* effect of oxygen is to produce a species of *passivity* at the points actually reached by it; but the *indirect* effect is to cause *corrosion* at the points not reached directly.

The corrosion set up by these differential aeration currents becomes most serious when the unaerated anodic area is much smaller than the aerated cathodic area, since then the whole effect is concentrated on a limited surface, and the rate of penetration downwards will be quite rapid. If a minute cavity exists in the metal and becomes filled with liquid, this will be relatively inaccessible to diffusing oxygen, and will therefore become anodic to the main portion of the surface; the attack will here quickly eat down into the metal, causing 'pitting.' The mouth of the pit will become covered with a loose hump or blister of rust, due to interaction of the anodic and cathodic products, but since this rust is not formed *in situ* at the anodic area, it will not protect the metal from corrosion; on the contrary, by shielding the interior of the pit from oxygen, it will, for a time, tend to promote the attack. Thus, when once pitting has commenced, it is difficult to stop it.

Differential aeration currents probably constitute the most serious practical cause of corrosion of zinc, iron, steel, lead, and aluminium articles. But electric currents set up in any other way will cause corrosion, provided that the immediate anodic and cathodic products are soluble bodies; where—as in the case of lead in a sulphate solution—the direct anodic product would be an insoluble compound, there is comparatively little attack.

Numerous other ways of generating these corrosion

[2] American Chemical Society Corrosion Symposium, 1925. See *Ind. Eng. Chem.*, 17, 1925, 370.

[3] This yellow colour is due to the characteristic tint of ferric hydroxide, and in no way resembles the yellow temper colour.

[4] *J. Chem. Soc.*, 127, 1925, 2605.

currents are known. In the case of copper, if water is moving rapidly over the surface at one place and is comparatively stagnant elsewhere, the copper ions will be carried away more quickly from the point of rapid motion than from the rest of the surface, and therefore a concentration cell is set up; the point of rapid motion is anodic and suffers corrosion. Where a material consists of two phases, a current may flow between these two phases, even when the composition of the liquid is the same everywhere. This is possibly the reason why—as mentioned above—a steel disc suffers alteration even under conditions of uniform aeration; for though—by whirling—we may diminish or even eliminate differential aeration currents, we can still get currents set up between the iron and carbide particles of the steel. Owing to the fact that under conditions of whirling the individual anodic and cathodic areas are of microscopic, instead of macroscopic, size, the hydroxide is precipitated close to the surface, and tends to cling to it. Thus the rust produced under these conditions of uniform aeration is far more adherent than that produced by differential aeration.

Climatic Changes during Geological Times.[1]

By C. E. P. BROOKS.

II. CAUSES OF GEOLOGICAL CHANGES OF CLIMATE.

THE preceding article closed with a discussion of Wegener's theory of continental drift. That theory is still *sub judice*, but it was pointed out that even if it be ultimately accepted, it does not solve the problem of climatic changes. Köppen and Wegener themselves recognise this, for they adopt astronomical changes as an explanation of glacial and interglacial stages, and suggest also that astronomical changes may have been important in the Tertiary succession of Europe. Apart from this, however, any one looking at Wegener's reconstructions and remembering the way in which the land and sea distribution at the present day dominates the local distribution of climate, cannot but realise that these extensive rearrangements must have brought about corresponding changes of climate, quite apart from those due to the supposed changes of latitude. Köppen and Wegener implicitly assume that the distribution of climate depends only on the distribution of solar heat at the outer limit of the earth's atmosphere, but even if the radiation from the sun be supposed to have remained constant, there are many factors of climate other than the astronomical conditions. These factors have been discussed in a large number of books and papers which include some very brilliant work. This great mass of literature is surely worth a thought.

In the middle decades of the nineteenth century, when radio-activity had not been discovered and pre-Quaternary glaciations were a heresy, the earth was believed to be cooling from an original molten state and the uniform warmth of the earlier geological periods was attributed to this earth-heat. In this scheme of things the Quaternary glaciation—"The Great Ice-Age"—marked the gap between the waning of earth-heat and the assumption of full control by the sun. This primitive view is no longer tenable, but still it occasionally crops up, as in the ingenious speculations of Marsden Manson, who supposes that the internal heat maintained the oceans at a high temperature, thus giving rise to a dense mantle of cloud which shut out the heat of the sun. The earlier ice-ages were due to local cooling in the centres of the great continents, the Quaternary to the final cooling of the seas, while the introduction of the present zonal distribution occurred when the last remnants of the universal cloud layer broke down.

Another early theory of climatic changes, variations in the heat received from the sun, perished from lack of evidence. Dubois attempted to bolster up his hypothesis that during the Quaternary glaciation the sun was a red star by arguments from colour blindness regarded as an ancestral trait belonging to the time when the earth was bathed in a perpetual sunset glow. Other views attributed the Quaternary ice-age to the shutting out of the sun's heat by a cloud of cosmic dust, and one ingenious theory gives us an ice-age for the birth of each planet between the earth and the sun. Recently Huntington and Visher[2] have attempted to revive the theory of solar control. Starting from the accepted view that the earth is slightly warmer at minima of the eleven-year sunspot period than at maxima, and the controversial view that storminess increases from minima to maxima of sunspots, they suppose that the warm periods were times of few sunspots and the ice-ages times of many sunspots. Such an enormous extrapolation from a small and imperfectly understood basis would not be warranted unless supported by convincing evidence. At present we know nothing of the variations of solar activity during the geological past, and even if the variations which Huntington and Visher postulate have actually occurred, it is improbable that they would have the results which are attributed to them.

Whatever may be the case with the total radiation received by the earth in a year, there can be no doubt that its distribution in seasons and latitudes has varied greatly with changes in the obliquity of the ecliptic and in the eccentricity of the earth's orbit. The idea that these changes were responsible for geological changes of climate is very old, but it was not until the appearance of Croll's brilliant essay, "Climate and Time," that they won general respect. Croll supposed that the most favourable conditions for glaciation occurred during times of great eccentricity, and were located in the hemisphere with winter in aphelion, the short hot summer being insufficient to melt the accumulated snowfall of the long cold winter. Murphy first pointed out that the reverse was more likely to be true, and subsequent research has confirmed Murphy's view. Although the total quantity of heat received over a whole hemisphere in a year is not affected by astronomical changes, this is not true of individual belts of latitude, and in high latitudes more heat is received in the course of a year when summer falls in

[1] Continued from p. 17.

[2] Huntington, Ellsworth, and Visher, S. S., "Climatic Changes: their Nature and Cause." New Haven, 1922.

perihelion than when summer falls in aphelion. Moreover, the summer conditions are of greater importance for glaciation than are the winter conditions.

This astronomical theory of climatic changes has to face two great difficulties. First, it requires glaciation to alternate in the northern and southern hemispheres, while geologists believe that glacial stages have been synchronous over the whole world; and secondly, the astronomical time-scale is incompatible with the geological time-scale as set out in the absolute chronology of de Geer. Recently, means have been found to overcome the first of these difficulties; thus R. Spitaler,[3] after an elaborate computation of the temperature of land and sea in different latitudes under a great variety of astronomical conditions, considers that each stage of the Quaternary ice-age represents a time of maximum eccentricity covering several precession periods of 21,000 years each, the ice-sheets advancing when aphelion fell in spring or summer and retreating when aphelion fell in autumn or winter, but being able to persist through the whole stage owing to the general cooling of the oceans. Spitaler's scheme, however, requires much more time than the geologists will allow. W. Köppen[4] attributes a similar persistence to the cooling introduced by the ice-sheets themselves; on the basis of calculations by M. Milankovitch, in which the heat received in summer is regarded as the essential variable, he achieves a more moderate time-scale, which, however, still presents several difficulties. Thus Spitaler and Köppen make the main glacial stages synchronous in each hemisphere, but with secondary maxima at different times. The astronomical theory has this in its favour, that we can be reasonably certain that the postulated astronomical changes have occurred. But if they were of such dominant importance during the Quaternary, it is curious that they have not been recognised in the climatic alternations of earlier geological periods—for example, there should have been several ice-ages at intervals during the Tertiary. If until the Quaternary they were masked by much greater effects due to non-astronomical factors, why not attribute the Ice-Age itself to the latter also?

The interval between the founding of the astronomical theory by Croll and its recent revival has witnessed the birth and death of the carbon dioxide theory, introduced by Arrhenius[5] in 1896 and taken up by F. Frech, T. C. Chamberlin and others. The theory is that carbon dioxide acts like the glass of a greenhouse, allowing the sun's rays to reach the earth's surface almost unchanged, but absorbing the greater part of the return long-wave terrestrial radiation. Subsequent research has shown, however, that water-vapour has exactly the same properties, and that there is always sufficient water-vapour present to absorb practically all the radiation which would be taken up by carbon dioxide, so that the latter can play only a very minor rôle.

Chamberlin introduced another remarkable conception—the reversal of the oceanic circulation.[6] Ocean currents are due to three causes, differences of temperature in different parts of the surface, differences of salinity, and the action of the wind on the surface layers. At present the latter cause predominates, the warm surface waters of the tropical oceans being driven westwards and then polewards by the prevailing winds. Chamberlin supposed that at times the evaporation in the inter-tropical regions was so great that the surface layers, owing to their increased salinity, became heavy enough to sink to the bottom, where their heat was conserved as they spread polewards, until they emerged in high latitudes and brought about mild polar climates. The chief objection to this is that great evaporation implies also heavy rainfall, while the periods in which the mild polar climates prevailed are marked by aridity in middle latitudes.

Somewhat less sensational variations in the system of ocean currents have frequently been adduced as causes of climatic change. The remarkable difference of climate between the British Isles and Labrador is usually attributed to the fact that the former are washed by the warm Gulf Stream Drift, the latter by the cold Labrador Current, and it has been supposed that the opening of a gap between North and South America, by allowing the warm water of the Guiana Current to pass through into the Pacific, caused the Quaternary ice-age in Europe. This particular conclusion is not warranted by the premises, but from the great differences of climate which can exist between places along the same parallel of latitude, it is obvious that the redistribution of land and sea may account for considerable changes of climate. This was the view of Lyell, who attributed the Quaternary ice-age to an expansion of the tropical oceans, from which much water was evaporated, and in high latitudes an extension of the land areas, on which the water-vapour fell as snow. Similarly, W. Ramsay[7] has insisted on the importance of high ground in lowering the temperature, not only locally but also over the whole world. Such ideas must remain speculative, however, until they have been supported by an adequate numerical basis.

F. Kerner has done more than any one else to calculate what effect a given change of land and sea distribution would have on the local and general temperatures; his results show that geographical changes go a long way towards accounting for the climatic vicissitudes of Europe during the Tertiary,[8] but he failed to account for the mild Arctic climates of the Jurassic and Eocene, his calculated January temperatures for the 75th parallel being nowhere above the freezing-point.[9] One of Kerner's papers, however,[9] contains a suggestion of what may ultimately prove to be the most important factor in climatic changes, namely, the cooling power of an ice-covered polar ocean. Brooks had previously shown a similar cooling power of land ice; when an ice-sheet reaches certain dimensions, the cold ice-winds bring the neighbouring land below the snow line, and the process continually repeated enables the ice-sheet to grow to very large dimensions. Calculations show that the extension of

the Scandinavian ice to England, and the rapid collapse of the ice-sheets at the close of the Quaternary glaciation, are accounted for by this effect. A floating polar ice-cap can be dealt with in the same way; at the close of a warm period the ocean will remain entirely free of ice until the temperature falls to freezing-point in winter. A small further fall, and a floating ice-cap will spread over the whole of the polar ocean. Kerner's and Brooks's calculations indicate that a general rise of temperature by 5° F. persisting over many years would suffice to render the whole Arctic Ocean non-glacial, a change which would reverberate over the whole globe.

This idea entirely alters the scale of the problem. Many factors which are inadequate to account for the temperature change of some 40° F. in the polar and cold temperate regions between an ice-age and a warm period may easily account for a change of 10° F., the remaining 30° being due to the cooling power of land ice and sea ice. Only two types of climate are possible, the 'non-glacial' or warm and the 'glacial' or cold. The transition from one to the other may be due to any of the climatic factors which have been so ardently advocated, but the close association between cold climates and mountain-building suggests the dominance of geographical causes. After a major orogenic period the continents are high and extensive, the ocean currents are restricted, and perhaps volcanoes send out large quantities of dust to interfere with the free passage of the sun's rays; all these causes, combined perhaps with unfavourable astronomical conditions, lower the amount of heat reaching high latitudes, so that the temperature of the polar oceans falls below the freezing-point in winter and a floating ice-cap is formed. After a long period of rest and erosion, the continents are low and small, there is a free oceanic circulation, and volcanoes are unknown; so much heat reaches high latitudes that the polar oceans are above the freezing-point even in winter, and there is no ice.

What of the Upper Carboniferous glaciation of the tropics? The geographical theory can be indicated only briefly; it postulates a high plateau, with a cold ocean to the south, a warm ocean to the north, and a permanent 'south-west monsoon' blowing from the former to the latter, covering the plateau with a dense layer of low cloud which with the assistance of a volcanic dust veil reflected a large proportion of the sun's rays back to space and kept the temperature low enough for snow to fall abundantly above a level of about 6000 feet, giving rise to ice-sheets which reached the sea. Whether the difficulties which confront this theory are greater than those confronting the theory of continental drift which is its only alternative, time will show.

Recent Developments in the University of Sheffield.

ON July 1 and 2 the University of Sheffield celebrated the twenty-first anniversary of the granting of its charter of incorporation. Congratulatory addresses were presented by sister universities throughout Great Britain and the Dominions, scientific and other institutions and societies, and public bodies. Among the recipients of honorary degrees may be mentioned H.R.H. Princess Mary, Lord Derby, Sir Austen Chamberlain, Sir Charles Eliot, Prof. P. F. Frankland, and Engineer Vice-Admiral Sir Robert B. Dixon. New engineering and metallurgical laboratories were formally opened by Sir Robert Hadfield, and the numerous delegates and other visitors were afforded an opportunity of acquainting themselves with the work of the various departments.

The University of Sheffield received its charter twenty-one years ago, but the history of the institutions out of which it grew goes back much further. The Technical School, the germ of the present Applied Science Department, was founded in 1886; Firth College, from which the faculties of arts and pure science took their origin, dates from 1879; while the Medical School will be able to celebrate its centenary in 1928. These three institutions united in 1897 to form the University College of Sheffield, which received full university status in 1905. The history of the University during the past twenty-one years has been one of almost unbroken progress in every direction. The numbers of its students and staff have greatly increased, especially since the War; the amount of research work carried on within its walls has grown steadily; new departments and courses have been established as the need for them arose and the resources of the University permitted; and generous financial support has been received from private and public sources. Though a complete survey of recent progress is not possible here, a few notes on the main lines of development may perhaps be not without interest.

The most rapid and extensive progress in recent years has taken place in the Department of Applied Science, which includes the faculties of engineering and metallurgy, and a number of associated departments. Expansion in these branches has been made possible largely by the growing recognition in industrial circles of the importance of technical training and scientific research. Thanks to the generous support of leading Sheffield industrialists, the departments of the faculty of engineering have been able to make several important additions to their resources. The Edgar Allen and Jonas Research Laboratories, opened in 1923, are designed respectively for research in magnetism, magnetic properties of materials, and allied subjects, and for investigations on the mechanical properties of materials. Further provision for research in this latter subject has been made in the new laboratory opened by Sir Robert Hadfield on July 2, which is being used at present for work on the effects of high temperatures, heat treatments and repetition stresses, but can be adapted, as the need arises, for the investigation of many other engineering problems. All these new laboratories are equipped with the most modern machines and apparatus, constructed in many cases in the engineering workshops.

One of the most important post-War developments is the establishment, in association with the faculty of engineering, of a Department of Fuel Technology. This

is essentially a research department, and the majority of its students are honours graduates in chemistry. It co-operates closely with the mining and metallurgical departments, and has entered into a working arrangement with the Safety in Mines Research Board and the Fuel Research Board, whereby the facilities for research work at the disposal of each body are shared mutually, and the respective staffs engage in conjoint work. Among the subjects that have particularly engaged the attention of the department have been the properties and production of blast-furnace coke, the constitution and properties of coal, and problems of gaseous combustion.

The Mining Department, an integral part of the faculty of engineering, has also made rapid progress, especially on the research side of its work, which has dealt chiefly with flame-proof electrical apparatus, coal-cutter steels, winding and haulage ropes, and mine ventilation. The Department has co-operated with the Safety in Mines Research Board and with the mining industry of the surrounding area. Its work has grown to such an extent that the present accommodation is inadequate, and a scheme is in hand for the erection in the near future of an entirely new mining department.

No account of the progress made in applied science would be complete without a reference to the Department of Glass Technology, which is equipped with a complete glass works, and laboratories in which a large body of research has been carried out. In connexion with the Department there has been formed the Society of Glass Technology, with a membership of about 650, distributed through twenty-two countries.

The faculty of metallurgy has existed separately since 1917, but the subject has played a leading part in the activities of the Applied Science Department since its earliest days. Owing to the nature of the chief industries of Sheffield, the needs of which it was originally created to serve, the faculty chiefly concentrates on the metallurgy of iron and steel, and it is now the best equipped in the country for work in this sphere. Recently, in response to the growing interest in scientific research among the lighter industries of the city, increasing provision has been made for non-ferrous metallurgy. A notable feature of the activities of the Department is the close association of practical training with theoretical instruction. Its equipment includes a complete steel works, fitted with plant of sufficient capacity to produce open-hearth, crucible and electric steels for the use of both the Metallurgical and Engineering Departments. Recent developments include the provision of a new laboratory designed specially for post-graduate research work on the physical properties of steel, and the institution, with the aid of a grant from the Department of Scientific and Industrial Research, of research work on electro-deposition, which will be of great importance to the Sheffield plating trades. Other Government departments and research associations maintain research workers in the metallurgical laboratories.

Though the rapid expansion of the Applied Science Department has been a notable feature of the recent history of the University, considerable development in other directions can be recorded. There has been a great increase in both teaching and research work in the faculty of pure science. Chemistry has had to extend its laboratory accommodation by the erection of a large hut in the quadrangle, and there has been a steady output of research, carried out largely with the aid of students, which has been concerned mainly with investigations on the reactivity of substituents in the benzene nucleus, the remarkable isomerism of diphenyl derivatives, and adsorption by porous bodies. Physics also has been compelled to provide for its enlarged teaching work by the erection of a hut, and has further acquired four new research rooms. The research work carried out in the Department has followed the line, laid down originally by Emeritus Prof. W. M. Hicks, of specialisation in spectroscopy, and a very considerable equipment in this branch of physical study has been gathered together.

In the faculty of medicine three recent developments are worthy of notice. There have been, in the first place, changes in the curriculum and organisation of the faculty, with the object of bringing both its teaching and research work into closer contact with the city hospitals. Anatomy and physiology, formerly taken for the second M.B., Ch.B. examination, have been extended into the third M.B., Ch.B. course, and thus, during the third and part of the fourth year, theoretical work in these subjects is carried on simultaneously with clinical training. A series of posts in physiology and pathology, the holders of which work both in the University and in the hospitals, has been created. An important part in linking up the teaching work of the University with the clinical part of the medical course is played by the Department of Pharmacology, established in 1921, which has devoted itself to extensive investigations on subjects of combined laboratory and clinical interest. In addition to the accommodation at the University, the Department possesses a field laboratory in the country, specially created for experimental work on nutritional and other problems. The opportunities for medical research provided in the Department have resulted in a large output of work, including amongst other subjects the etiology and treatment of rickets, the factors of diet and environment responsible for the structure of the teeth, conditions controlling the rate of development of caries in children, the treatment of exophthalmic goitre, the action of alcohol and the toxic action of cereals. The third line of development in the medical work of the University has been the re-establishment of the dental school, in connexion with which new laboratories, provided with the most modern equipment for the teaching of dental mechanics, have been opened. A complete course of instruction for degrees and diplomas in dental science has been arranged, and hospital accommodation for clinical work is provided.

The foregoing notes, though they mention only the most important developments of recent years, show that Sheffield has taken its place side by side with the other universities of Great Britain, as an institution actively engaged both in the propagation and in the expansion of knowledge. The main lines of expansion which it is destined to follow are laid down, and further progress may confidently be expected as funds become available.

News and Views.

THE King's birthday honours list, publication of which was delayed on account of the General Strike, was issued on July 3. It includes the following distinctions conferred in recognition of scientific services or association with scientific work:—*Privy Councillor*: Sir Halford Mackinder—chairman of the Imperial Shipping and Imperial Economic Committees and first Principal of University College, Reading, now the University of Reading. *K.B.E.*: Sir Frank W. Dyson, Astronomer Royal; Prof. W. Somerville, late Sibthorpian professor of rural economy, University of Oxford. *D.B.E.*: Dr. Mary A. D. Scharlieb, consulting gynæcologist, Royal Free Hospital. *Knights*: Colonel H. G. Lyons, Director and Secretary of the Science Museum; Dr. Brajendra Nath Seal, Vice-Chancellor of the University of Mysore. *C.B.* (*Civil Division*): Dr. G. C. Simpson, Director of the Meteorological Office; Mr. F. E. Smith, Director of Scientific Research, Admiralty. *C.M.G.*: Dr. A. W. Hill, Director, Royal Botanic Gardens, Kew, Mr. J. O. Shircore, Director of Medical and Sanitary Services, Tanganyika Territory. *C.B.E.*: Mr. A. Abbott, Chief Inspector of Technical and Continuation Schools, Board of Education. *O.B.E.*: Mr. E. W. Wallis, secretary of the Royal Sanitary Institute. *I.S.O.*: Mr. D. d'E. de Charmoy, Assistant Director and Entomologist, Agricultural Department, Mauritius; Mr. A. R. Wright, assistant comptroller, Patent Office.

THE Commonwealth House of Representatives has passed two Bills dealing with the reconstitution of the Institute of Science and Industry. The Bills received the hearty approval of members on all sides of the House, the sole complaint from the Opposition (Labour) being that their introduction had been unduly delayed. The first Bill outlines the scheme of reorganisation, which abolishes the former directorship and provides for a central council composed of three members appointed by the Governor-General (who will constitute an executive committee and exercise all the powers of the council between meetings), the chairman of the six State advisory committees, and such other members as the council may desire to co-opt on account of special scientific knowledge. A sum of 250,000*l.* is appropriated for the purposes of the council, and this will ensure that for the first few years its programme will not be subject to yearly modification to accord with the exigencies of the Treasury. The name "Institute of Science and Industry" has been discarded, and the body will in future be known as the "Council for Scientific and Industrial Research," which is more in accord with British and Canadian practice. The second Bill establishes a Trust Fund of 100,000*l.*, the income from which is to provide assistance (*a*) to persons engaged in scientific research, and (*b*) in the training of students in scientific research. Considerable progress has already been made by the executive committee in the preparation of proposals for the first session of the new council, which will commence on June 22. It is hoped to establish very close relations with the British Department for Scientific and Industrial Research, and to that end the chairman of the executive committee (Mr. G. A. Julius) will visit Britain towards the end of this year.

THE Mellon Institute of Industrial Research is a good example of what can be done by the co-operation of enlightened manufacturers and by able administration. Its system of industrial fellowship was initiated in 1906, and although this remained in the experimental stage for nine years, since 1915 it has been in a strong position both financially and administratively. Dr. E. R. Weidlein, the director, states in his recent report that fifty-four of these fellowships, employing ninety-four research chemists and engineers, were held in the Institute during the year ended February 28, 1926, and that more than 125,000*l.* was contributed for their maintenance by the fellowship donors. The total sum of about 775,000*l.* has been received from companies and associations during the last fifteen years. In a separate document the Institute issues a list of the contributions made to scientific literature and of patents taken out during 1925. This list is of formidable length, but what strikes one most is the exceedingly practical nature of the majority of the investigations pursued and their great diversity. Problems relating to coal, coke, and petroleum are, perhaps, most conspicuous, but there is also a goodly array of contributions relating to metallurgy, refractories, laundering, and foodstuffs.

DR. WEIDLEIN has also written an essay entitled "The Administration of Industrial Research" (*Industrial and Engineering Chemistry*, January 1926), in which he discusses the various factors that make for success in the conduct of a research organisation, such as the selection of research workers, organisation, co-ordination of effort, and the virtues of team work. The principles involved in the management of a research laboratory are set out on the lines of Taylor's "Principles of Scientific Management," and "the functions of laboratory organisation" are analysed in detail. The essay may be recommended for perusal by directors of research; it will interest them, although they may not find it entirely convincing. Many of the 'principles' and 'functions' enumerated appear to be obvious, not to say platitudinous, and one is left with the impression that an organisation in which every entity and activity, physical, moral and intellectual, is dissected, described, catalogued, charted and labelled, is scarcely the place where the free spirit of scientific adventure can dwell with patience or good will.

DR. WEIDLEIN is undoubtedly on strong ground when he pleads for a proper business foundation for every institution devoted to industrial research, but we foresee trouble if, as he advises, the activities of a research department are "adjusted constantly to suit the needs of the concern," or if the research worker becomes too intent on "keeping in line with psychological laws." Some of the author's *obiter dicta* are also open to question. We can, for example, hear

Candide and the initiators of gas-warfare chuckle when they read: "If a scientist is productive in his investigations, his work must result for the good of humanity"; and we do not think that Schiller, who wrote that "talent is formed in quietude, character in the current of the world," would have agreed with the assertion that "The character of virtue is best seen in the life of a scientist devoted to the service of research."

ON Thursday last, July 1, unfortunately too late for insertion in our issue of July 3, we received the following telegram from Prof. W. H. Keesom, of the University of Leyden: "Helium solidified under a pressure of 150 atmospheres at the temperature of its boiling-point and under 28 atmospheres at 1·5° Abs. Solid helium forms transparent mass." This achievement thus rounds off the work of the late Prof. H. Kamerlingh Onnes, begun more than thirty years ago. By his extraordinary energy and organising ability Kamerlingh Onnes built up his cryogenic laboratory in Leyden, and in 1904 was able to obtain supplies of liquid air. By 1906 he was liquefying hydrogen on a large scale, and in 1908 he succeeded in liquefying helium. This enabled him to obtain a temperature of 4·22° Abs., and by reducing the pressure the temperature was further reduced to 0·9° Abs. Attempts were made with the pressure so low as 0·2 mm. to solidify helium but without success, and it has remained for Prof. Keesom, apparently using an increased pressure method, to complete the work which 'the master' left unfinished.

To all interested in navigation the problem of the issuing of suitable signals at danger spots in the ocean or near the coast is of the greatest interest. There are many spots where it is too expensive to provide a keeper to attend to the light and fog signals, where also, on account of the rocky bottom, strong tides, and ships' anchors, it is impracticable to maintain a submarine cable connexion. It is interesting to hear, therefore, that the Marconi Company has established an unattended fog-signal station on Rosneath Beacon on the Firth of Clyde. It was installed last January and its working has proved very satisfactory. The control is by radio waves, and we see no reason why the same method should not be applied to control other kinds of mechanical apparatus acting at a distance. Rosneath Patch is a sandbank in mid-channel at the mouth of the Clyde between Gourock and the opposite Argyllshire coast. A reinforced concrete beacon marks the Patch. Automatic apparatus has now been installed which gives signals by exploding a mixture of air and acetylene gas. Once started, the 'guns' continue giving explosions until they are switched off or until the acetylene gas is exhausted. These guns are the only automatic signals at present in use, being cheap to install and maintain. At Rosneath Beacon they get their supply of acetylene gas from a carbide-to-water plant. A radio receiving apparatus is fitted and is synchronised with the transmitting set on Gourock Pier, 1¼ miles from the Beacon. When fog is observed, the transmitting apparatus is put into operation and the radio impulses act on the receiving apparatus. The signals being periodic prevent atmospherics acting on the receiving set. When the fog clears, another set of periodic impulses having a different period is transmitted and stops the signals. The annoyance to the neighbourhood is thus reduced to a minimum. The essential features of the sending apparatus are a pendulum and mercury break, a spark coil and a quenched spark transmitter.

THE Cretan earthquake on June 26 has been followed by others in various parts of the world, on June 28 in Sumatra and Rhineland, on June 29 in southern California and at Salisbury in southern Rhodesia, and on June 30 by another in Sumatra. In a letter published in the *Times* of June 30, Prof. Turner places the epicentre of the Cretan earthquake in 35° 0′ N. lat., 24° 0′ E. long., or just south of Crete, the same spot having been the seat of seven smaller earthquakes between 1913 and 1922. The damage at Candia and in some of the surrounding villages was considerable, including injury to many of the remains from Knossos collected in the Candia museum. A telegram from Rome, dated June 28 states that more than two thousand houses have been destroyed by earthquake-shocks in several villages in the province of Foggia in southern Italy, but these shocks can scarcely be connected with the Cretan earthquake, even if they occurred on the same day. The earthquake in Rhineland at 11 P.M. on June 28 was evidently felt over a wide area, at Cologne, Freiburg and other places in Germany, at Basel and Bern in Switzerland, and at Strasbourg, Epinal and Belfort in France. Though few details are as yet known of the Sumatra earthquake of June 28, it was clearly one of great strength, for many villages have been destroyed, and the railway and main roads near Padang have been much damaged. One of the most interesting of the recent earthquakes was that in southern California on June 29. At Santa Barbara it was strong enough to cause some very slight damage. It was probably an after-shock of the destructive earthquake in the same district on June 29, 1925 (NATURE, 1925, July 11, p. 56, and August 29, p. 324).

THE Royal Air Force display, such as was seen at Hendon on July 3, is more spectacular than the old *Kaisermanöver* and more exacting than Fleet exercises, and sums up from year to year the visible progress in design, operation, and discipline. A hundred and thirty aeroplanes in the air during the day, with half-a-dozen out of action from minor causes, is a remarkable achievement of design and maintenance. Types ranged from the 700 h.p. single-seat fighter, with corresponding speed and climb, to the eight-ton twin-engine bomber (900 h.p.), and the three-engine 20-seat commercial aeroplane (1000 h.p.). 'Acrobatics' by individual pilots, squadron drill with nine aeroplanes, orders being given by radio telephony, and group drill with six squadrons, stirred the layman to loud applause and the expert to deep appreciation. The Hill tailless aeroplane and the first British-built Cierva autogyro might be considered as outward signs of the work of the Director of Research, which

also lies less directly and visibly behind all manner of detail advances in standard equipment. From this pageant and from day to day work we may judge soberly that the British Air Service is holding its own in a keenly competitive world.

SIR FLINDERS PETRIE, in a letter to the *Times* of July 2, reports on the work of the British School of Archæology in Egypt during the past season. The investigations of Mr. R. S. Sandford on the history of the Nile during the pluvial period, carried out in the region between Thebes and Sohag, have linked the gravels carried down from the eastern granite mountains with palæolithic man. Starting from a gravel terrace at 150 ft., the 100-ft. terrace was laid down during the Chellean and early Acheulean period, the 50-ft. terrace in Acheulean times, while the latest gravel terrace at 10 ft. above river level contains Mousterian implements. Miss Thompson, continuing her work in the Fayum, has found, in addition to crude pottery and a large number of flint arrow heads and knives, a new feature in the form of granaries situated at a higher level. These are about 3 ft. across and sunk in the gravel. They are lined with coiled straw rope. The grain was mostly emmer and barley, but also included true wheat. Investigation of the tumuli on the island of Bahrein in the Persian Gulf by Mr Mackay produced scanty results, but a bronze spearhead indicates a date of 1200–1500 B.C., which is supported by the character of the pottery. The forms of the pottery include Mesopotamian types, but the greater part is entirely independent. The work on the back of an ivory statuette is like nothing known elsewhere.

THE weather for the second quarter of the year, April-June, was generally wet, cool, and dull in the British Isles. Warm and bright weather at this season is so essential for vegetation that a few facts gathered from the Greenwich weather observations, which represent the south-east of England, may help to show the absence of fair conditions. The rainfall was in excess of the average in each month, yielding an excess of 3·66 in. for the three months ending June. April was mild, but the latter part of the month was colder than the early part; April 25 and 26 had maximum day temperatures below 50°, and for seven days from April 20-26 the maximum day temperature was below 54°, the normal maximum for the month being 57°. May was unusually cold for the first 20 days, and during this period the maximum temperature was only above 60° on 4 days; the highest day temperature was 63°. Warmer weather set in after the third week, which brought the mean temperature for the month to 52°·5, which is only 1°·5 below the normal. In June only 8 days at Greenwich were above the average, and 22 days were below the average temperature. The absence of bright sunshine was evidently the cause of the continued cool weather. April had sunshine for 101 hours, which is 3·37 hours a day, or 1·65 hours a day less than the normal; there were only 11 days with more than 5 hours' sunshine, and in all, only 6·4 hours' sunshine in the last 11 days of April. May had 149 hours' sunshine, which is 4·81 hours a day, or 1·66 hours a day less than the normal. In June the total sunshine was 180 hours, or 5·99 hours a day, which is 0·71 hours a day less than the normal.

THE evolution controversy in the United States still sends echoes across the Atlantic. The *Forum*, an American periodical for an intelligent but non-specialising public, has in its June issue a reply by Prof. H. Fairfield Obsorn to an article attacking the "Fancies of the Evolutionists," by John Roach Straton, which appeared in February last. Prof. Osborn sets out to demonstrate "certain irrefutable facts" constituting the evidence for the geologic antiquity and creative evolution of man. The article is both a summary of present knowledge relating to the origin, evolution, and distribution of mankind, and a history of discovery in this province of research, necessarily in both cases brief and in outline only. The accusation of a conspiracy among evolutionists is met by a statement of the fact that in the case of crucial discoveries, such as that of the Trinil skull or Neanderthal man, the interpretation which assigned them the place in the human evolutionary series which they now hold was not immediately and universally accepted by scientific men. Further, Prof Osborn points out that the experience of a hundred and fifty years, or on some matters of centuries, has brought the methods of scientific research in this field to such a point that the evidence can be interpreted with certainty and precision. The data are not "blurred or indecipherable documents like the palimpsests of many sacred writings, but are absolutely unchallengeable records as clear as daylight to the man who has learned how to read them" —a statement to which Prof. Osborn's own article may perhaps suggest some slight reservation. The existence of a fact is indisputable, but what of its interpretation? Prof. Osborn himself did not at one time accept the human attribution of the Piltdown jaw. However, his position is sound, and the main argument is not to be shaken by a minor inconsistency.

MR. HERBERT KRIEGER, of the United States Museum, while on his way to south-eastern Alaska, where he will carry on the work of restoration of the totem poles of that area, has made a survey of the pit-house sites of the old Yakima and Klickitat Indians of the Columbia River region of the State of Washington. This area would appear to have supported one of the densest populations in early America. Mr. Krieger reports the existence of a chain of house-sites stretching for 500 miles along the banks of the Columbia from the Dalles in Oregon to the Canadian border. The river was undoubtedly one of the great trading centres and routes of travel. Eight skeletons and forty-five artefacts were obtained by excavation in a burial ground. The artefacts showed no sign of Hudson Bay Company influence. The skulls exhibited cradle-board deformation similar to that of neighbouring tribes of to-day. Pictographs cut in the basalt cliffs of the river bank showed shields, bows, arrows, goats, big-horn sheep, and

designs suggestive of the rising sun, lightning, and so on. It is perhaps worth mention that Mr. Harlan I. Smith has recently recorded pictographs, which these would appear to resemble, found in a similar position in British Columbia.

THE *Times* of June 29 contains an interesting account of the recent Hokkaido eruption written by its Tokyo correspondent. Like some other Japanese volcanoes, Tokachi has two peaks. One of them has a fairly well-defined crater with its north-east wall denuded or blown away. The other, known as Iwo-dake or sulphur mountain, had a small crater occupied by a lake. On May 7 the mountain, supposed to be extinct, showed some signs of activity: slight rumblings were heard and a small column of steam was emitted. On May 23 the rumblings, which had continued, became more pronounced, and on the following day the crater of Iwo-dake was breached by the rising lava-column, a large portion of the crater-wall fell down the mountain-side, and the water of the lake was released. The resulting destruction and loss of life were caused chiefly by the avalanche of mud, which swept over an area ten miles long with a maximum width of four miles. Its force is shown by the fact that at Kami Furano a mile and a half of the railway line was torn away and twisted like wire. When the water subsided, an area of ten square miles of highly cultivated rice land was left covered by a layer of sandy mud with an average thickness of 18 inches.

WE must all deplore the disappearance of examples of English architecture dating from the Middle Ages and later which is rapidly taking place in our villages owing to economic and social development. The awakening of public interest in this matter is tardy and spreads but slowly among those in whose hands control is vested. Sir Frank Baines's lecture on "The Preservation of Ancient Cottages," delivered before the Royal Society of Arts on May 6 last and now published in that Society's journal, is opportune, and should be made widely known. As he points out, the ancient workman's cottage is not merely a thing of considerable beauty; it is almost the sole piece of tangible evidence we possess of the social and economic position and of the material conditions of life among the peasant population from the Middle Ages up to the seventeenth and early eighteenth centuries The lecture, as published, is illustrated by photographs of a large number of examples of this class of domestic architecture. Of these, the number which have now disappeared, among them some of the most beautiful and characteristic, is in itself an eloquent argument for the urgent necessity of early action.

DR. F. A. BATHER, president of the Geological Society, will unveil a mural tablet to William Smith on July 10 at 29 Pulteney Street, Bath. After the unveiling ceremony, there will be a luncheon at the Guildhall, to be followed, in the afternoon, by an address by Dr. Bather at the Royal Literary Institution on William Smith and his work.

SIR ERNEST RUTHERFORD (Cambridge), Sir Frederick Hopkins (Cambridge), Prof. H. A. Lorentz (Haarlem), and Dr. H. L. le Chatelier (Paris), were elected foreign members of the Académie Polonaise des Sciences, Cracow, last year. In conformity with the statutes of the Academy, such elections have to receive the sanction of the president of the Republic of Poland. We are glad to know that this has now been given, and that the elections can be announced.

SIR JAGADIS C. BOSE, founder and director of the Bose Research Institute, Calcutta, who is at present in England lecturing and giving experimental demonstrations on plant stimuli and responses, has been elected president of the Indian Science Congress to be held in Lahore in January next.

ROYALTY has always been credited with the parentage of anecdote, but we hope that this one is genuine. A charming young American, having met the Prince of Wales at a reception, asked him to tell her how he ought to be addressed, as, for example, on an envelope. The Prince—says the story—took her programme and wrote upon it: "To His Royal Highness, The Prince of Wales, K.G., F.R.S."

UNDER the title of "Illumination Research," the Department of Scientific and Industrial Research has issued a pamphlet, which will be supplied gratis on request, in which the work of the Illuminating Research Committee appointed in July 1923 is described. At the present time the following problems are under investigation: The transmission of light by window glass, the effect of the colour of the walls of a room on the light in the room, the use of prismatic glass in the windows, the lighting of picture galleries, the effects of enamel reflectors as used in works, the effect of glare on the eye and the influence of the amount of light on the ease and accuracy with which fine work can be done. The pamphlet does not deal with finance, but there are few who would care to challenge the expenditure of a few thousand pounds in this way in order to determine how best to get value for the millions of pounds spent annually in Great Britain on illumination.

WE have received the "Classified List of Publications of the Carnegie Institution of Washington" dated December 1925. This, with its detailed abstracts, is itself a publication of some value; but it does not appear to indicate clearly those works that have been issued since the distribution of the previous list.

WE have recently received volume 3, for 1924, of the *Publications biologiques de l'École des hautes Études vétérinaires*, Brno. Ten contributions are contained therein; in the index they are paged consecutively, but in the text, pagination commences afresh with each paper, a much less convenient arrangement. Botanical problems of development are dealt with, by Staroštík, on the bud of *Ficaria verna* and the influence of external agents on its growth, by Pavlů on the histology of the beet, and by Václavík on correlation between cotyledon and axillary bud in the pea. The other seven papers are zoological or physiological, again with emphasis on the experimental study of development.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A lecturer in experimental physiology in the University of Manchester—The Internal Registrar (July 14). A junior lecturer in mechanical and electrical engineering and a junior lecturer in geography at University College, Nottingham—The Registrar (July 17). An organiser of mining instruction for Derbyshire—Director of Education, County Education Office, S. Mary's Gate, Derby (July 17). A research chemist for work on plasters and other materials used for impressions and models in dentistry—Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, Westminster, S.W.1 (July 21). An assistant at the Commonwealth of Australia Observatory at Mount Stromlo—The High Commissioner for Australia, Australia House, Strand, W.C.2 (July 22). A temporary assistant chemist at the Naval Ordnance Inspection Depôt, Holton Heath—Secretary of the Admiralty (C.E Branch), Admiralty, Whitehall, S.W.1 (July 24). An assistant lecturer in pure mathematics at the University College of Wales, Aberystwyth—The Secretary (July 28). Temporary assistant chemists in the Government Laboratory—The Government Chemist, Clement's Inn Passage, Strand, W.C.2 (July 31). An additional zoologist for the *Discovery* Expedition—The Secretary, *Discovery* Committee, Colonial Office, Downing Street, S.W.1 (July 31). A junior technical officer for the wireless experimental department of the Royal Aircraft Establishment—Superintendent, R.A.E., South Farnborough, Hants (July 31, quoting A.79). A botanist for the agricultural department of the Government of Nigeria—Private Secretary (Appointments), Colonial Office, 38 Old Queen Street, Westminster, S.W.1 (August 15). A director of the Veterinary Laboratory of the Ministry of Agriculture and Fisheries at New Haw, Weybridge—The Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1 (November 1). A director of research under the Research Association of British Paint, Colour and Varnish Manufacturers—Mr. J. B. Graham, 8 St. Martin's Place, W.C.2. A man with teaching experience in physics, chemistry and mechanics—Cordwainers' Technical College, St. John's Lane, E.C.1. An assistant at the Darlington Technical College, chiefly for geometrical and engineering drawing, and either engineering science or mathematics—Chief Education Officer, Education Office, Darlington. An advisory agricultural economist at the Midland Agricultural and Dairy College, Sutton Bonington, Loughborough—The Principal.

Our Astronomical Column.

LARGE SUNSPOTS.—The naked-eye sunspot recently noted in these columns was followed shortly afterwards by the appearance of another which was seen as a naked-eye object from June 26 until July 1. In a small telescope, the spot appeared elongated with a double umbra, there were several small companions near it and others in a cluster following at some distance. Details of position, etc., are given below in the usual tabular form. This latest spot brings the total number of naked-eye spots to eight for the first six months of 1926, as compared with eight for the whole of the preceding year.

No.	Date on Disc.	Central Meridian Passage	Latitude	Longitude	Area.
8	June 23–July 5	June 29·2	21° N.	140°	1/1250

(Area expresses the proportion covered of the sun's hemisphere.)

PONS-WINNECKE COMET AND METEORS.—Mr. W. F. Denning writes: "Announcements emanating from Russia have been published to the effect that a meteoric shower might occur between June 24 and July 1. The fact that the parent cause, Pons-Winnecke's comet, would be situated at a distant point of its orbit, which it occupies twelve months before perihelion, robbed the prediction of any weight that it might otherwise possess. It is true that in 1916 there was a meteoric shower ten months after the comet had passed its perihelion, but there were great doubts as to whether the cometary materials were abundant at a spot so remote in front of it. The result of observation was anticipated, for though June 24-30 proved fairly clear, few meteors could be seen in the brilliantly moon-lit skies of the period.

Meteoric observers will anticipate a shower next year with more confidence and with conditions which appear to be favourable. Even in 1928 there may be many meteors seen, judging from the experiences of 1916, which showed that they were distributed far behind the comets. Probably also the stream is spreading out with time, and that even if the ellipse is not at present continuous it will ultimately assume that form.

The brightest meteor lately seen was on June 27, $23^h\ 20^m$ G.M.T. The meteor was moderately slow and about equal to Jupiter: duration, 2 sec. The probable radiant was in Sagitta and far from that of the Pons-Winnecke comet. The meteor was also observed by several other persons in Bristol, and they mention it as giving a distinct flash like summer lightning."

NOVÆ.—The *Observatory* for June contains a detailed summary of the paper read by Dr. J. Lunt on Nova Pictoris at the May meeting of the Royal Astronomical Society. The radial velocity indicated by the dark lines gradually increased, being (in km./sec.) −71 in 1925 May, −81 in early June, −92 in late June, 320 July to August, −395 in mid-September, −411 in January, −436 in March. Bands resembling those in η Argus began to appear in October, and gradually became more evident. The nebular bands customary in the later stages of novæ did not appear until March. Dr Lunt endorses the words of Prof. Hartmann's telegram to *Astr. Nachr.*, "The star swells up and bursts." He considers that the star was discovered at the simmering preparatory stage, and that the explosive ebullition came later. The cause is conjectured to be a release of atomic energy within the star.

F. Pingsdorf of Parana (Argentine) gives a series of measures of brightness of the nova. The following summary gives the magnitude at the beginning of each month: December $4·2^m$, January $4·3^m$, February $4·6^m$, March $5·1^m$, April $5·4^m$, May $5·5^m$. The star thus remained an easy naked-eye object for a year, which is longer than most recent novæ, though less than Tycho's famous star.

Beobacht. Zirk. No. 23 contains a note by Prof. M. Wolf on his faint nova in the spiral nebula N.G.C. 4303 (Messier 61). He obtained two photographs on June 1 that show a marked diminution of light since discovery on May 12. Its magnitude was then about 14^m, and 15^m on June 1; on the latter date it was $0·2^m$ fainter than the star south preceding the nucleus at a distance of 1·3′. This rapid decline makes the American estimate of the star's total light as being 10 million times that of the sun appear somewhat doubtful.

Research Items.

DEPOPULATION AND DISEASE IN THE NEW HEBRIDES.—Dr. P. A. Buxton, of the London School of Hygiene and Tropical Medicine Expedition to the South Pacific, in a communication to the Royal Society of Tropical Medicine and Hygiene, which is published in vol. 10, No. 8, of the *Transactions* of that Society, discusses the question of depopulation in the New Hebrides and examines the evidence bearing on the statement generally made as to the extent to which this is due to diseases introduced by Europeans. Depopulation appears to be going on rapidly on all the islands except Tanna, Aniwa, and the north part of Pentecost. On Tanna, Tonga, Tongariki, and Buninga, numbers are stationary or rising, and on Futuna and Aneityum they may have reached their lowest and begun to rise. A calculation based on figures going back as far as any records are available for the five islands Aneityum, Aniwa, Futuna, Erromanga, and Epi, shows that there is no consistent rise or fall throughout the period, which in one case goes so far back as 1865. This seems to imply that the principal causes of depopulation were as active in the last century as now. To some extent the decline may be due to native customs—the institution of gerontocracy, which reserved marriageable females to the old males, abortion, a practice which repression of polygamy tends to increase, wars, belief in magic, bad housing, and unsuitable feeding of infants. The evidence of pedigrees shows an actual decrease in the birth-rate. The recruitments of native labour carried off the younger men as well as introduced disease. Of diseases, the most serious are malaria and yaws, but dysentery and pulmonary diseases play an important part. Two disquieting facts are that the rate of decline is no less now than it was fifty years ago, notwithstanding the abolition of 'blackbirding' and the reduction in the severity of epidemics, and that about 118 males are born per hundred females, this disproportion persisting through life. These facts almost warrant the prediction of the eventual extinction of many of the races now living in the New Hebrides.

THE ARTIFICIAL PRODUCTION OF LUSTRE ON FLINT IMPLEMENTS.—Mr. W. J. Lewis Abbott, 8 Grand Parade, St. Leonards-on-Sea, writes to say that he has discovered a process which simulates the somatic change in flint implements responsible for the production of the high glaze usually accepted by archæologists as a criterion of age. He points out the inapplicability of the term 'patina'—in origin a term used to describe the surface lustre of bronze—to all the various types of metamorphosis to which flint is subject. These metamorphoses are either superficial or somatic. The high glaze which arises from the superficial metamorphosis is due to attrition and can be produced artificially by sand-blast or running water charged with sand. The somatic metamorphosis in Nature is practically confined to the vitreous variety of flint, although it sometimes occurs in the normal and very rarely in the cryptogranular. In mixed flint it will appear in the vitreous and stop at the cryptogranular. The black, almost opaque flint becomes like a slightly clouded, otherwise colourless, clear hyalite, more brilliant and transparent than 'Hungarian' opal, taking the most brilliant colours in the presence of various salts of iron. The metamorphosis takes place below the surface and works towards it until the conversion is complete, or it may occur in excessively small islands. The specimen may retain its elasticity, but if this is lost, it is obvious that the implements were made before the alteration set in. This form of metamorphosis has now been produced artificially. Flint—vitreous, normo-vitreous and normal—fashioned into implements by Mr. Abbott himself, has been submitted to a certain process which has entirely opalised it, with the result that the nearly opaque flint is now translucent, of various shades of brown, and has a most brilliant glaze. Specimens have been submitted to Sir Arthur Keith, who states that he has "never seen a richer or finer patina," and characterises Mr. Abbott's discovery as "very clever and dangerous."

FISH STOCKING IN AMERICA.—Mr. C. W. Creaser has recorded the results of successful attempts at stocking the upper waters of the Great Lakes with smelt, *Osmerus mordax* (*Michigan Academy of Science, Arts and Letters*, vol. 5, 1925). All the eggs used in the various stocking operations were from Green Lake, Maine; the smelt, which is a native of this lake, belongs to a freshwater race of the marine species common along the North Atlantic coast. Evidence is produced to show that transplantation of eggs, which was first started in 1906 and was continued in different years up to 1921, has led to firm establishment of the species, and that in some localities natural spawning has been going on for several years. Mr Creaser gives an interesting account of the spawning of this fish in Crystal Lake, Michigan; this takes place very early in the spring (April), before the ice breaks up in the lake as a whole. The fish move in a body into small streams; the main run is at night, most fish returning to the lake in the daylight. A vivid description is given of the solid masses of fish assembling to spawn. The fish were extremely susceptible to light, which they avoided; so strong was this reaction that the entrance of fish into the stream could be regulated by a flash-light. A reaction to currents was also exhibited. A note on the feeding habits of the smelt elicits the fortunate fact that the adults feed in the summer almost entirely on a species of minnow on which other fish do not feed, and that hence they cannot be regarded as serious competitors for food. Details of age determination by scale reading are given; the smelt first breeds at the end of its second winter.

BOT FLIES OF THE PUNJAB.—*Bulletin* 160, *Agricultural Research Institute*, Pusa, 1926, is devoted to an account of certain of the bot flies prevalent in the Punjab and is written by Captain H. E. Cross. A very common species, forming warbles in goats, is *Hypoderma crossii*, which infects 40-90 per cent. of those animals in the Salt Range area. The larvæ, pupa and adult of this species are described and figured, but the eggs have so far remained undiscovered. The ox warble, *Hypoderma lineatum*, and its occurrence in the Punjab is noted, and this appears to be the first record of its being found in India. The camel bot fly, *Cephalopsis titillator*, is widely distributed throughout the Punjab and various stages in its life-cycle are figured and described. This insect is viviparous and the first stage larvæ occur in the nostrils of the camel. When about 7 mm. long until fully grown they are met with in the pharynx and are finally expelled through the nostrils, pupation taking place in the soil a few hours later. So far as known, the species does not entail much injury to its host, but it is possible that it may cause *kapauli* (pus in the sinuses), which is a fatal disease. Among other species the common sheep bot, *Oestrus ovis*, the wild sheep bot, *Oestrus*, sp. nov. ?, the horse bot, *Gasterophilus equi*, are also dealt with. The bulletin concludes with a brief discussion of the injuries caused by these flies and of the methods of treatment.

THE SWAMP CYPRESSES.—The swamp cypresses, and particularly Glyptostrobus, are not well known in Great Britain, so that the taxonomic and anatomical notes by Prof. Augustine Henry and Marion McIntyre in the *Proceedings of the Royal Irish Academy* (vol. 37, B. 13, 1926) will serve a useful purpose. Glyptostrobus, the water-pine of the Chinese, they conclude, is a monotypic genus; this species being found only in two swampy localities in south-eastern China. The Chinese regard the presence of the tree as propitious to the rice crop, and the villagers resist its molestation, even by the photographer. *Glyptostrobus pensilis* is also one of the rarest cultivated trees in Europe, only one specimen growing in the open being known to the authors (at Nymans, Sussex). There are living plants under glass at Kew and Glasnevin. The three living forms of the much better known swamp cypress of America, Taxodium, are also passed in review as to macroscopic and microscopic characters of branchlets, leaves, flowers and cones, in order to permit a comparison with Glyptostrobus. In view of the necessity, often present to the palæobotanist, of distinguishing between genera on structural features alone, a comparative study of the wood of these two genera and also of Wellingtonia and Sequoia is included in the paper.

BIOCHEMICAL DIFFERENCES BETWEEN THE SEXES OF MUCORS.—In the Mucors, Blakeslee, in particular, has shown that in many species two sexual strains may be distinguished; individual mycelia of the same sex will not conjugate, whilst conjugation occurs freely between mycelia of different sex. These 'heterothallic' strains thus occur in sexual pairs, but the form and structure of one sex is practically identical with that of the other, and, apart from the behaviour on conjugation, the two sexes cannot be distinguished, except, perhaps, by a difference in vigour of growth. Blakeslee has provisionally designated these as (+) and (-) strains, the plus strain being the more vigorous when this growth distinction can be drawn. Sophia Satina and Blakeslee now report (*Proc. Nat. Acad Sci.*, Washington, March 1926), in a preliminary manner, upon a biochemical study of these Mucor sex strains. They conclude that the (+) and (-) races show significant, average, biochemical differences in respect to (*a*) the Manoilov reaction, (*b*) catalase content, (*c*) reduction of potassium permanganate by extracts of the mycelium, and (*d*) reduction of tellurium salts in living cells In a subsequent paper they apply biochemical tests to unisexual flowering plants, obtaining additional evidence in support of the conclusion that the female plant and the (+) strain of a Mucor show similar biochemical behaviour. A certain statistical element enters into this type of observation. As the authors put it, the general rule that the human male is the heavier is not vitiated by the fact that on chance selection of a human pair an especially buxom female might be put in contrast with a meagre male.

AGRICULTURE IN ARID LANDS.—In a paper on the struggle with arid conditions in the Volga region (*Matériaux pour l'étude des calamités*, No. 8, January-March 1926) Mr. N. M. Toulaikoff, who is director of the experimental station at Saratoff, makes several constructive suggestions for safeguarding agriculture against the arid conditions in the Volga region. An average rainfall of about 16 inches is small enough considering the summer heat, but it is not the slight total amount that natters so much as its irregularity in fall. While poor crops and want occur generally in years of deficient total rainfall, there have been instances of abundant crops in years of scanty rainfall. In those years the rain fell in the seasons demanded by the crop. The main crop of the peasants has always been summer wheat, which suffers severely from spring drought and cannot recover when the rains come so late as June and July. More satisfactory crops would be rye, which develops before the most usual period of drought, and maize, millet, sorgho, and beet, which develop in June and July and do not suffer from the prolonged heat of summer. A study of these problems has been made on experimental farms, and it is considered that the likelihood of famine could be minimised if not banished by adapting agriculture to the peculiarities of the climate.

GEOLOGY OF THE WEALD.—Among regional surveys now being carried out may be mentioned the work of the Weald Research Committee of the Geologists' Association. This consists of a geological survey on the 'six-inch' scale of the Weald, which is being actively pursued by the members of the Committee, who number about two dozen, each member having undertaken to survey the country comprised in at least one 'six-inch' sheet. It is just over fifty years since the survey by W. Topley was published by the Geological Survey, but while our knowledge has been extended locally, no general geological survey has been attempted previous to the initiation of this committee. No point of geological interest is being neglected; the petrology as well as the palæontology of the beds is being worked out in detail, while a good start has been made in the complex problems involved in the denudation of the area. This branch of the work will occupy a considerable time, but some points of interest are already being elucidated; for example, a late Pliocene terrace discovered in the Mole gap has produced widespread planation in the district especially north of Ashford. The Committee has very properly not set itself any definition of the Weald, for its researches must extend well beyond the region to which the name applied originally. In this connexion the gravels of Rayleigh in Essex may be cited. These contain pebbles of Lower Greensand chert, which may have been derived from the Weald through the Medway gap, and if this proves to be the case the pebbles travelled across what is now the lower Thames.

THE TRAVEL OF DEPRESSIONS.—The *Meteorological Magazine* for April gives an interesting and descriptive account by Lieut.-Col. E. Gold, assistant director of the Meteorological Office, on the foregoing subject. The article should prove most instructive to meteorologists not well versed in the new ideas relative to cyclones which are proving of immense value to the weather forecaster, either official or otherwise. From the initiation of forecasting, cyclonic depressions have necessarily proved almost the controlling feature. The movement of cyclones in the British Islands and their vicinity differs so widely, and the area controlled or affected varies so considerably, that it seems almost impossible to forecast effectively. The development by Bjerknes of the idea of cold and warm sectors in the individual cyclones separated by definite surfaces of discontinuity has enabled the Bergen school to divide cyclones into different classes according to their stage of development. They draw a distinction between (*a*) cyclones which have a definite warm sector with definite lines of separation from the cold sector, and (*b*) cyclones in which there is no warm sector at the surface of the earth. Class (*a*) are generally growing cyclones which usually move with increasing speed as they grow, and Class (*b*) are dying cyclones which tend to become stationary. In Class (*a*) the centres of the cyclones move in the direction of motion of the air in the warm sector, and approximately with

the speed of motion of the warm air; a diagrammatic representation is given of such a cyclone. A description is also given of Class (*b*), in which there is no warm sector. Cyclones of Class (*a*) eventually lose their warm sector and change into Class (*b*); the warm sector only disappears at the earth's surface, the warm air being lifted up by the colder air, and the discontinuity will continue to exist at greater heights. The author alludes to the difficulty of giving in so short an article anything like a complete account of the technical investigations, but his mastery of the subject has suggested much which is helpful to the less initiated.

ELECTRON EMISSION ENERGY WITH OXIDE CATHODES.—In the *Zeitschrift für Physik* of April 30, Herr H. Rothe describes a series of measurements on a number of triode valves with oxide cathodes in which the energy of emission of the electrons was determined, using Richardson's equation, and also by means of the cooling effect produced by the emission. The values found by the two methods, which agreed quite well with one another when the emission current was saturated, were exceedingly small. The relation between the emission from such cathodes and the amount of gas removed from them was investigated. It seems that it is not possible to free oxide cathodes from gas perfectly; apparently the emission current which passes through the oxide layer radially decomposes the oxide and so constantly produces new gas. The author considers that the high emission of these cathodes depends on the metal particles, produced by this decomposition, which remain embedded in the oxide. It is noted that if the emission current is below the saturation value the cooling effect is considerably greater than that corresponding to the energy of emission. A fatigue phenomenon has been investigated, which in almost all the tubes caused the emission current to fall off rapidly with the time.

THE PALLADIUM-HYDROGEN EQUILIBRIUM.—The absorption of hydrogen by palladium has been the subject of much experimental study since it was first reported by Graham, and the results of the latest investigation by L. G. Gillespie and F. P. Hall appear in the *Journal of the American Chemical Society* for May 1926. They describe a method of securing equilibrium by means of a new heat treatment, and the isotherms which they determined indicate the presence of two solid solutions At the higher temperatures the solution richer in hydrogen is said to consist of a hydride Pd_4H_2

SILVER IODIDE IN GELATIN IODO-BROMIDE EMULSIONS.—R. B. Wilsey has recently found, in studying the crystal structure of mixed crystals of silver iodide and bromide, that the cubic lattice characteristic of silver bromide has some of its bromine replaced by iodine with an enlarged lattice spacing when it is crystallised with silver iodide. But when the iodide is present to the extent of about 40 per cent. or more, there was a second lattice spacing corresponding to that of silver iodide. Emery Huse and C. E. Meulendyke of the Kodak Research Laboratory (*Journal of the Royal Photographic Society*, June, p. 306), have sought to fix the proportion of silver iodide present when it begins to form separate crystals from a mixture of the two salts. A series of gelatin emulsions was prepared containing increasing quantities of iodide, and exposures in a spectrograph were developed physically, as silver iodide is scarcely amenable to alkaline development. The physical development of silver iodide gives a very sharp-edged sensitivity limit at wave-length 440 mm., and as the iodide was increased this first appeared when the iodide constituted 32 per cent. of the mixed haloids, and remained as the iodide was increased, and was entirely lacking at 30 per cent. or less. The authors therefore conclude that silver iodide separates in emulsions of this type as definite crystals, apart from the silver bromide, when the silver iodide content reaches approximately 32 per cent.

HELIUM IN NATURAL GASES OF JAPAN.—The thirteenth report of the Aeronautical Research Institute, Tokyo Imperial University, published early this year, contains an account of an examination of natural gases from Taiwan, Hokkaido, Honsyu and Kyusu, primarily for helium, by Messrs. Y. Kano and B. Yamaguti. The gas samples were taken from various sources, such as oil reservoirs, coal-mines, mineral springs and volcanoes, and were analysed for helium by Cady and McFarland's method, for other constituents by Hempel's standard method The purity of the helium was tested spectroscopically. Carbon dioxide, sulphuretted hydrogen, oxygen, carbon monoxide, methane, ethane, nitrogen and heavy hydrocarbons were among the chief constituents of the gases investigated, and from the analytical results it has been possible to classify the natural gases into three types rich in carbon dioxide, in hydrocarbons and in nitrogen respectively; as in the case of helium in American natural gas, the percentage of this element is highest in nitrogen-bearing gas. The helium content of some mineral spring gases examined reaches 0·2-0·3 per cent., but unfortunately the amount of gas available from this source is strictly limited and insufficient for industrial purposes; very small quantities of helium were found in the gas from the Taiwan and Hokkaido areas, where it is associated with petroleum, the average being 0·005 per cent, again an impracticable amount for commercial purposes. The oil and gas reservoirs of Taiwan and Hokkaido are of Tertiary age, from which the low helium content of the gas from these sources is accordingly explained The authors find that the percentage of helium in a hot spring gas depends to a certain extent on emanation content, though no direct ratio could be established, this agreeing with McLennan's conclusions with regard to Canadian natural gas. Samples containing no helium generally possess the least radioactivity, and this to some extent supports the theory that the origin of helium in natural gas is to be ascribed to disintegration of radioactive substances; if this is so, then it is clear that the geological age of a gas reservoir is an important criterion of helium possibilities.

SIZES OF AERODROMES.—It is a matter of some considerable importance to determine the size of aerodrome necessary in order that a landing may be made on it if engine failure occurred at any time during getting off. In an interesting paper by H. Glauert to the Aeronautical Research Committee (R. and M. 996, pp. 10. London: H.M. Stationery Office, 1926, price 6*d*.), this question is investigated more especially in the two cases: (1) where the aeroplane continues in its original direction after the engine failure; and (2), where the aeroplane, climbing on a steady turn, on failure swings back into the wind. A comparison of the results of these two cases shows that an important saving in the necessary size of the aerodrome can be secured by the turning climb, but the size of aerodrome indicated is larger than that of current practice unless the stalling speed and power loading are limited. Curves are given showing the necessary size of aerodrome in terms of stalling speed and power loading of the aeroplane. In particular, the required size of the aerodrome was found to decrease as the angle of climb increases and as the stalling speed decreases.

The Chemical Constitution of Thyroxine.

ALTHOUGH the stimulant action of the thyroid gland upon the general metabolism of the body has been recognised for more than a generation, yet it is only within the last decade that the isolation of a pure crystalline principle, possessing the stimulating effects of the whole gland, has been successful. This was first accomplished by Kendall in 1914; since then this author has described a number of the derivatives of the pure substance, which he called "thyroxin," and has suggested a structural formula for it. Our knowledge of it has now been carried a step further by Harington, who has improved the method of extraction so that it gives a much higher yield than Kendall's method, and has proceeded, with the larger amount of material thus available, to determine its chemical constitution by methods of degradation and synthesis. Although at present synthesis has only been carried to the penultimate stage, there is every reason to hope, considering the way in which the author has unravelled the constitution of this compound, that the complete synthesis will soon be successful.

Before describing Harington's work, a few words may be said about the physiological properties of thyroxine. This subject, together with some recent work on its derivatives, has been reviewed by Kendall in his Chandler lecture ("Influence of the Thyroid Gland on Oxidation in the Animal Organism." By E. C. Kendall. New York: Columbia University Press; London: Oxford University Press, 1925. Price 3*s.* net). The activity of thyroxine in stimulating metabolism is remarkable: 1 mgm. injected intravenously in a patient suffering with myxœdema will increase the basal metabolic rate 2.5 per cent., corresponding to an increased output of 400 gm. carbon dioxide; the effect is, within limits, proportional to the dose. Moreover, the time relations of the response are characteristic. Thus, in a normal adult there is a latent period of six to eight hours; thereafter the metabolic rate rapidly increases but the maximum is not reached until the eighth or tenth day. The metabolism then returns slowly to normal, the rate of fall depending on the amount present in the body. A dose of 5-10 mgm affects the metabolism for five or six weeks. It can replace the administration of dried thyroid gland in the treatment of cretinism and myxœdema; in a normal person, not only is the metabolism increased, but also the signs and symptoms of over-activity of the thyroid gland are also produced. Under normal conditions the thyroxine formed in the body appears to be responsible for about 40 per cent. of the metabolism, since complete thyroid deficiency causes a drop in the basal metabolic rate of this order.

The principle of the method of extraction from the thyroid gland is hydrolysis with alkali, followed by precipitation of the filtrate with acid, but whereas Kendall used 5 per cent sodium hydroxide, Harington found that 10 per cent. barium hydroxide resulted in a greatly increased final yield (C. R. Harington, *Biochem. Journ.*, vol. 20, 293, 1926). After about six hours' boiling of the dried thyroid in ten volumes of alkali, 60-70 per cent. of the total iodine appears in the filtrate; 40 per cent. of this can be precipitated on acidification as a creamy flocculent precipitate. The latter requires further hydrolysis with the alkali, when about half the iodine remains in solution and half is carried down with the insoluble barium salts; the latter contain the thyroxine. The precipitate is boiled in alkaline sodium sulphate solution to remove the barium and the filtrate precipitated with acid. The precipitate of crude thyroxine can be further purified by solution in alcohol made alkaline with caustic soda and re-precipitating with acetic acid. Further material is obtained from the gland residues by boiling with caustic soda, adding sodium sulphate, filtering and precipitating the thyroxine in the filtrate with acid. After re-crystallisation, by dissolving in alkaline alcohol and adding acid, further purification is effected by dissolving in dilute hot sodium carbonate, when the sodium salt separates out on cooling. This is re-dissolved in alkaline alcohol and the thyroxine precipitated with acid. The pure substance crystallises in rosettes and sheaves of fine needles. On heating, it darkens at 220° C. and melts with decomposition and evolution of iodine at 231°-233° C. It is insoluble in water and organic solvents; it is soluble in cold dilute solutions of alkali hydroxides, but insoluble in acids. It is soluble in 90 per cent. alcohol with the aid of either alkali hydroxide or mineral acid. The yield was about 0.027 per cent. of the fresh, or 0.12 per cent. of the dried gland, corresponding to about 14 per cent. of the total iodine originally present; Kendall's yield was 0.0011 per cent. of the fresh gland. The physiological activity of the material extracted by Harington's method was shown to be the same as that of thyroxine prepared by Kendall's process.

The compound contains 65.3 per cent. iodine; analysis led to the empirical formula $C_{15}H_{11}O_4NI_4$; Kendall's formula is $C_{11}H_{10}O_3NI_3$, and the difference between the two is due to the fact that Harington found a lower nitrogen content than Kendall. The former observer confirmed his analysis, however, on a commercial sample of thryoxine prepared according to Kendall's process. Kendall considers thyroxine to be triiodo-dihydro-oxindole propionic acid; Harington considers it to be the tetraiodo substitution derivative of the parahydroxy-phenyl ether of tyrosine.

The arguments in favour of the latter appear conclusive: the products of disintegration of the molecule have been identified; the foundation of the molecule has been synthesised and only requires the addition of the iodine atoms to become identical with the original thyroxine. The first step in the breakdown of the molecule is the removal of the iodine; this Harington accomplished by shaking a dilute alkaline solution in an atmosphere of hydrogen with a palladium hydroxide–calcium carbonate catalyst. The iodine was split off as potassium iodide, and the hydrogen taken up was exactly equivalent to the iodine removed. The resulting compound was called desiodo-thyroxine (*Biochem. Journ.*, vol. 20, 300, 1926). Its formula was found to be $HO . C_6H_4 . O . C_6H_4 . CH_2 . CHNH_2 . COOH$.

The interest of the subject appears to justify a somewhat detailed account of the successive steps in the disintegration and synthesis of desiodo-thyroxine. The facts that the latter gave positive Millon's and ninhydrin reactions, and that all the nitrogen was present as amino nitrogen, suggested that the compound was an α-amino-acid with at least one phenolic group; the proportions of carbon and hydrogen suggested the presence of two benzene rings. Fusion with potassium hydroxide produced parahydroxybenzoic acid, quinol in varying amounts according to the conditions, ammonia, oxalic acid, and a substance with the formula $C_{13}H_{12}O_2$. The latter possessed only one phenolic group; the experiment thus suggested the presence of two benzene rings, one of which has a phenolic group in the para position to a side chain, from which a two-carbon fragment is split off as oxalic acid.

Exhaustive methylation of desiodo-thyroxin gave

a product which lost trimethylamine on boiling with alkali and yielded an unsaturated acid, $C_{16}H_{14}O_4$, containing only one methoxyl group. On oxidation with potassium permanganate, oxalic acid and $C_{14}H_{12}O_3$ were formed; the latter was found to be an aldehyde which on further oxidation yielded an acid $C_{14}H_{12}O_4$. Thus methylation shows that desiodo-thyroxin is almost certainly an amino acid, and that it contains only one phenolic group; the splitting off of oxalic acid suggests the presence of a three-carbon side chain. Now fusion with potash led to the conclusion that two benzene rings are present; if linked through a carbon atom, a ketone should have been formed instead of an aldehyde on oxidation of the methylated product; hence they must be linked either directly or through the oxygen atom, which is still unaccounted for. Considering the latter supposition the more probable, the author proceeded to meet the degradation by synthesis.

The steps in the disintegration by exhaustive methylation and in the subsequent synthesis may be rendered clearer if the following structural formulæ are given:

Desiodo-thyroxin. $HO.C_6H_4.O.C_6H_4.CH_2.CHNH_2.COOH$.
$C_{16}H_{14}O_4$ (unsaturated acid) $CH_3O.C_6H_4.O.C_6H_4.CH:CH.COOH$.
$C_{14}H_{12}O_3$ (aldehyde) $CH_3O.C_6H_4.O.C_6H_4.CHO$
$C_{14}H_{12}O_4$ (saturated acid) $CH_3O.C_6H_4.O.C_6H_4.COOH$.
$C_{13}H_{12}O_2$ (from potash fusion) $HO.C_6H_4.O.C_6H_4.CH_3$.

The starting-point in the synthesis was parabromanisol, $CH_3O.C_6H_4.Br$; on condensation with the potassium salt of paracresol in the presence of copper bronze, 4 (4′ methoxyphenoxy) toluene, $CH_3O.C_6H_4.O.C_6H_4.CH_3$, was formed. On boiling with hydriodic acid, the compound $C_{13}H_{12}O_2$ was produced, whilst on boiling with permanganate the toluene compound was oxidised to the corresponding benzoic acid, $C_{14}H_{12}O_4$.

The complete synthesis of desiodo-thyroxin was carried out by a slightly different route; parabromanisol was condensed with potassium phenate to give (4′ methoxyphenoxy)-benzene, from which, by the hydrocyanic acid method, the aldehyde $C_{14}H_{12}O_3$ was obtained. The latter could be oxidised to the acid $C_{14}H_{12}O_4$. From the aldehyde both the acid $C_{16}H_{14}O_4$ and desiodo-thyroxin were synthesised; two methods were used in the case of the latter. The aldehyde was condensed with glycine anhydride in the presence of acetic anhydride and sodium acetate; the product on boiling with hydriodic acid and red phosphorus underwent simultaneous reduction, demethylation and hydrolysis, with the production of desiodo-thyroxin. In the alternative method the aldehyde was condensed with hydantoin, which on boiling with the same reagents yielded the desired product.

As regards the position of the iodine atoms in thyroxine, the author considers that it is probable that two are present in each benzene ring, in each case lying on either side of and next to the oxygroups, *i.e.* in the 3, 5, 3′, 5′ positions. The details of the final synthesis will be awaited with interest.

Annual Visitation of the National Physical Laboratory, Teddington.

On Tuesday, June 22, the General Board of the National Physical Laboratory made its annual visitation of the Laboratory. As in previous years, a large number of members of scientific institutions, technical societies, Government departments, and industrial organisations were also invited to be present. The visitors were received by Sir Ernest Rutherford, president of the Royal Society and chairman of the General Board, and the Director.

The extensive programme of exhibits illustrated well the comprehensive nature of the work which the Laboratory undertakes

In the 14-foot wind channel a model of the Cierva autogyro, which has aroused so much interest in aeronautical circles, was undergoing test. The model is mounted on three supports forming an inverted pyramid. The vertical forces on the feet of these supports can be measured, enabling the three component forces on the model to be determined, and quantitative data to be obtained for comparison with the conventional type of aeroplane. Another exhibit showed experimental arrangements for the investigation of the spinning characteristics of a model aeroplane. The model under test is mounted on an axis parallel to the wind direction in such a manner that its incidence can be varied. Examination of its behaviour permits the main features of the spinning motion to be studied so that it is possible to indicate what features in design are undesirable from this point of view.

In one of the smaller wind channels experiments were in progress to determine the convective dissipation of heat from the surface of an aerofoil in a wind current. Thin strips of platinum foil cemented to the entire aerofoil and parallel to the span can be heated electrically. Their temperatures can be determined by resistance measurements and equalised by adjustment of the currents traversing them. Measurements of their resistance and of the currents determine the rates of loss of energy from the individual strips.

A new 1-foot wind channel has been added to the equipment of the Department. This is intended primarily for the development and calibration of instruments for measuring wind speed and direction.

Among the exhibits of the Metallurgy Department were eight samples of British Standardised Steel, issued jointly by the Iron and Steel Institute and the National Physical Laboratory. These comprised four carbon standards containing respectively 0·10 per cent., 0·27 per cent., 0·65 per cent., and 1·00 per cent. of carbon, two sulphur standards containing respectively 0·027 per cent. and 0·071 per cent. of sulphur, one standard containing phosphorus (0·029 per cent.) and one manganese (0·66 per cent.). These standards are prepared from fine millings taken from six-inch bars Millings taken from the outer layers and the core are rejected, samples of the remainder being subjected to analysis by the Laboratory and various co-operating authorities.

Specimens of pure elements prepared in the Department were also on view. Mention may be made of two of these with which some advance has been made, namely, beryllium and silicon. The former is prepared by the electrolysis of a mixture of the fluorides of beryllium, sodium, and barium, a rotating cathode being used. This is slowly withdrawn at a predetermined rate with the pure metal adhering Special precautions are taken to prevent contamination of the metal by enclosing the salts in special crucibles. Specimens of these made of magnesia and alumina were shown in the foundry. For work on the constitution of silicon-aluminium alloys and on age hardening in aluminium alloys, very pure silicon is required. Samples were shown of 99·8 per cent. purity. Another exhibit illustrated the microscopic examination of metals usually liquid at ordinary temperatures. Such materials as are used in dental practice are included in this category. By surrounding them with a freezing mixture of carbon dioxide snow and acetone, it is possible to polish the surface to the degree requisite for microscopic examination.

In the William Froude National Tank a model self-propelled single screw vessel was shown under test. Simultaneous measurements were recorded of propeller thrust, shaft revolution, and distance travelled. These enable the propeller torque and power expended under varying conditions produced in the tank to be compared, and permit the losses due to the propeller, hull, and sea conditions to be apportioned.

In the Engineering Department research was in progress on the mechanical properties of metals and alloys for use at high temperatures, such as are experienced in modern steam engines and gas engines. At high temperatures metals generally used undergo continuous creep under steady loads, lower than those obtained in normal tensile stress determinations. Experimental work is being done to determine the rate of creep of such materials at various temperatures. For this purpose the test pieces are surrounded by an electric furnace maintained at the required temperature, a steady load being applied by a lever system. Any elongation can be measured by means of micrometers attached to the apparatus. Fatigue can also be studied in a special machine in which the stresses are produced by means of an alternating current, the specimen being heated in position by heating coils.

An investigation was also being carried out on the impact strength of chains. Normally chains are annealed periodically in order to counteract any tendency to embrittlement and the tests were designed with the view of determining the effect of this annealing on the strength of the chain. Of interest also was a trough in which the production of capillary and gravitational waves in water by means of a current of air acting on the surface was demonstrated.

In the Metrology Department, apparatus was shown for the absolute measurement of end gauges up to 4 in. in length. The gauge is converted into a Fabry-Perot étalon by means of two optical flats wrung on to its end faces, the flats having portions extending beyond the edges of the gauge, these portions being semi-silvered on their inside faces. When placed in a convergent beam of monochromatic light, interference fringes in the form of concentric circles are produced. Measurements of the angular diameter of such fringes in various monochromatic radiations enable the optical length between the two semi-silvered surfaces to be determined. The semi-silvered flats are produced at the Laboratory by the method of cathodic deposition, the glass to be silvered being placed near a silver cathode in a vacuum chamber. The apparatus employed for this purpose was on view. A monochromator, designed and constructed for use in connexion with interference measurements, was also exhibited.

In the workshop was apparatus for the study of the deformation of pivots under load. The pivot to be tested is mounted so that its point can be brought into contact with a flat sapphire by a balance arm. An image of the pivot is projected on to a screen and measurements made without and with a load in the balance pan, the magnification being 200 times.

A very large number of exhibits was shown in the Physics Department. Among these was apparatus for the determination of the thermal conductivities of materials at high temperatures by the measurement of the radial gradient in an electrically heated rod of the material.

A resistance bridge for platinum thermometry, made to the design of Mr. F. E. Smith and capable of measuring temperatures to 0·001° C., was exhibited. To obtain this accuracy special precautions are taken to control not only the temperature of the oil tank in which the coils are immersed but also the humidity of the oil, since this latter factor affects the resistance of the coils.

A new apparatus has also been designed for the purpose of measuring the change of length of 'constant length' type bubbles in spirit-level tubes under extremes of atmospheric temperatures likely to be encountered in surveying practice, namely, − 18° C. to 55° C. For this purpose an optical device is used by means of which both ends of the bubble are viewed simultaneously and brought into coincidence, the length being determined in one observation. In this apparatus special attention is given to the geometrical design of the moving parts and to the fine adjustments.

A variety of problems connected with refrigeration were being investigated for the Engineering Committee of the Food Investigation Board. These included apparatus for measuring the heat evolution in fruit by a process which may be compared with that of respiration in animals. In this apparatus a differential arrangement is used in which the heat evolved by apples is balanced by that from an electrical supply. For comparing the relative values of the resistance to indentations of specimens of cork slab and other heat-insulating materials, an apparatus has been constructed in which the depth of penetration of a steel ball about 3 in. in diameter is measured by a dial indicator.

Several forms of the Ewing ball and tube flow-meter were shown. In this instrument a glass or metal sphere is placed in a glass tube of conical bore and the displacement of the ball under the action of the flow of liquid is observed.

In the Optics Section was shown the "Vector" colorimeter, an instrument which enables colour to be specified by measurements involving colour-matching only. In use the colour to be tested is matched first against a mixture of extreme red with some suitable monochromatic light and then against a mixture of spectrum blue with another suitable monochromatic constituent. These matches determine two vectors on a colour chart and the intersection of these determines the unknown colour. Other apparatus included a flicker photometer for heterochromatic photometry and a spectrophotometer not involving polarising constituents.

In the Radiology Section was shown a new X-ray tube with detachable electrodes. In this tube, porcelain is substituted for the glass and the electrodes are fitted with rubber washers. The arrangement allows the tube to be dismantled for cleaning or other purposes and reassembled in a very short time. Apparatus for the study of the wave-forms of high tension generators by oscillographic methods was also shown working. By means of optical trains the wave-forms to be examined, together with a time curve from a tuning fork, are simultaneously recorded on a photographic plate.

In the Electrotechnics Department was shown a method of measuring high voltage dielectric loss. The Schering bridge is a capacity bridge specially suited for measurements of power losses at high voltages and small power factors; it ensures safety to the observer together with the accuracy attainable by other methods. Thus the method is applicable to the study of small phase defects in condensers. Power factors of 1 per cent. can be measured correct to 1 per cent. The dielectric loss in a cable at 20,000 volts was being investigated; in this application the vibration galvanometer and bridge operating arms need never be more than 2 volts above earth potential.

Research work was being carried out in the Direct Current Section on the earthing of electric circuits. Various forms of earthing electrodes suitably spaced are sunk in the ground, and their resistances determined

and compared under varying conditions of soil humidity.

In the Photometry Division a large integrating sphere 10 feet in diameter, constructed by the Metrology Department, was shown in use. It is intended primarily for the photometry of large illumination fittings. Apparatus has also been installed for the purpose of measuring candle-power by means of photo-electric cells. Light from the lamp under test falls on a rubidium cell mounted at one end of a photometer bench. A lamp mounted in a whitened cube, in the floor of which is a second cell screened from the direct light of the lamp, provides a suitable source for comparison. The cells, connected in series, are arranged to form part of a Wheatstone bridge and their currents are balanced by suitable adjustment of the illumination. In the illumination building experimental arrangements were shown for determining the daylight illumination in large or small rooms by means of models. Such information indicates the probable behaviour of their full scale prototypes with regard to daylight and is thus of value in architecture.

In the Wireless Division experience has shown the importance of complete screening of local oscillators and receivers from local electrical disturbances. Several pieces of apparatus, so protected, and including oscillators and receiving apparatus, a variometer and a model frame aerial, were exhibited. The knowledge has been used in the case of amplification tests on valve amplifiers. The amplifier under test and the local oscillator are both carefully protected, the former being placed in a specially screened room. Experimental work in connexion with short wave transmission is also being developed and various transmitting and receiving circuits were on view.

In the Electrical Measurements Department, in addition to the usual equipment, were various quartz piezo-electric resonators for use as radio frequency standards. These, on account of their constant frequency, are very suitable for the control of oscillators. One such oscillator with amplifying valves designed to produce radio frequency oscillations of great power and extremely constant frequency has been installed. L. J. C.

University and Educational Intelligence.

BIRMINGHAM.—The annual degree congregation was held on July 3. There were 6 successful candidates for the degree of Ph.D., 9 for M.Sc., 77 for the degree of B.Sc. with Honours, 48 for the ordinary B.Sc., and 24 for M.B., Ch.B. The degree of Doctor of Medicine was conferred on Gladys Mary Evans and Mr. Victor Goode Williams.

Dr. Laurence Ball, assistant to the chair of medicine and physician to the Queen's Hospital, has been appointed joint professor of medicine to fill the vacancy caused by the resignation of Prof. Kauffmann.

BRISTOL.—Sir George Wills, Pro-Chancellor and chairman of the Council of the University, has given 25,000*l*., to be used with the 110,000*l*. which he presented two years ago, for the erection of a residential hall for students.

CAMBRIDGE.—The Mayhew Prize in applied mathematics has been divided between J. A. Gaunt, Trinity College, and A. H. Wilson, Emmanuel College. The Rex Moir Prize in mechanical sciences has been awarded to H. L. Cox, Emmanuel College, and the John Bernard Seely Prize in aeronautics to R. E. Stevenson, St. John's College.

DURHAM.—Dr. Arthur Holmes, hitherto reader in geology, has recently been made professor of geology at Durham. Two new lectureships have been filled by the appointment of Dr. R. K. Schofield (physics), and of Dr. G. H. Christie (chemistry).

LONDON.—A University post-graduate travelling studentship of the value of 275*l*. has been awarded to Miss C. L. T. Lucas. Miss Lucas obtained the B.Sc. with honours in zoology as an internal student of Bedford College in 1923, and has worked since at the London School of Tropical Medicine. She proposes to carry out research on Amœbæ living in insects, chiefly at the Johns Hopkins University, Baltimore.

ST. ANDREWS.—The degree of D.Sc. in engineering has been conferred upon Mr. William John Walker for a thesis entitled "Developments of Engineering Thermodynamics. Analysis for Variable Specific Heat Conditions." Dr. Walker has resigned the post of lecturer in mechanical engineering and machine design held by him in University College, Dundee, having been appointed professor of mechanical engineering at the University of the Witwatersrand, Johannesburg.

PROF. A. E. MORGAN, professor of English language and literature in the University of Sheffield, has been appointed principal of University College, Hull.

DR. W. E. CURTIS has been appointed professor of physics and director of the Physics Department at Armstrong College, Newcastle-on-Tyne, in succession to Prof. Henry Stroud, who retires at the end of the present session. Dr. Curtis, who is at present reader in physics in King's College, London, was educated at the Imperial College of Science and Technology, London, and was for a time lecturer in physics in the University of Sheffield. He is the author of important papers on spectroscopy.

THE third Congress of the Universities of the Empire will be in session at Cambridge on July 13-16. The subjects for discussion and the names of the chairmen are as follows: "The State and the University," Lord Balfour; "The Desirability of establishing in London a School of Advanced Legal Studies," the Lord High Chancellor; "Co-operation in Research throughout the Empire," Lord Londonderry; "Mutual Recognition of Examinations and of Time spent in Study Elsewhere," Sir Matthew Nathan; "The Desirability of making Provision for the Physical Welfare and Training of Students and the Organisation of Athletics with a View to securing more general Participation," the Duke of Devonshire; "The Actual Working of the Ph.D. Scheme," Viscount Cecil of Chelwood; "The Desirability of Articulating other Pension Schemes with the Federated Superannuation System of Great Britain and Ireland," Lord Haldane. Among the invited speakers on "Co-operation in Research" are Sir Thomas Holland, Sir John B. Farmer, Sir Arthur Shipley, and Dr. Andrew Balfour; on the Ph.D. scheme, Mr. R. A. Priestley, Prof. Wenley, of the American University Union, Prof. Dobson of Bristol, and Prof. H. P. Newton, of King's College, London. Representatives of India, Australia and Canada, as well as Sir Alfred Hopkinson and Sir Theodore Morison, are among those who have promised to contribute to the discussion on "The State and the University." The sessions at Cambridge will be preceded by series of visits by delegates from overseas to all the other universities of Great Britain and Ireland. On July 12 there will be a Government luncheon in honour of the delegates, at which Lord Peel will preside, and in the evening they will have an opportunity of meeting the members of the second Anglo-American conference of professors and teachers of history at a reception given by the University of London.

Contemporary Birthdays.

July 10, 1854. Dr. George Lindsay Johnson.
July 11, 1857. Sir Joseph Larmor, F.R.S.
July 12, 1863. M. Léon Charles A. Calmette, For. Mem. R.S.
July 12, 1869. Prof. Charles Riborg Mann.
July 13, 1869. Prof. Frederick W. Gamble, F.R.S.

Dr. LINDSAY JOHNSON, whose studies in ophthalmology have had practical issues in South Africa as well as in England, was educated at Owens College, Manchester, and Caius College, Cambridge. He has written memoirs on the refraction and vision of the seal's eye; and on the pupils of the Felidæ. A monumental paper, brilliantly illustrated in colour, appeared in the *Philosophical Transactions* for 1901, entitled, "Contributions to the Comparative Anatomy of the Mammalian Eye, chiefly based on Ophthalmoscopic Examination."

Sir JOSEPH LARMOR was born at Magheragall, Co. Antrim, and educated at the Royal Belfast Academical Institution, Queen's College, Belfast, and St. John's College, Cambridge, of which College, since 1880, he has been a fellow. Following professional teaching in Ireland, he was for eighteen years a lecturer in mathematics in the University of Cambridge and in 1903 was elected Lucasian professor of mathematics. From 1901 until 1912 Sir Joseph was one of the secretaries of the Royal Society, a period of fruitful activities In 1915 he was awarded the Royal Society's Royal medal at the hands of Sir William Crookes, who remarked that the recipient's chief claim lay possibly in the establishment of the theory that radiant energy and intramolecular forces are due to the movements of minute electric charges. The theory was sustained in his treatise "Æther and Matter." In 1921 Sir Joseph was awarded the Copley medal. Mention should be made of his extended and masterly obituary notice of Lord Kelvin, published by the Royal Society in 1908.

M. CALMETTE, the accomplished assistant director of the Pasteur Institute, Paris, was born at Nice. Honorary professor of bacteriology and hygiene in the University of Lille, he is a commander of the Legion of Honour. In 1921 M Calmette was elected a foreign member of the Royal Society of London He is Hon. LL.D., Cambridge.

Prof. CHARLES R. MANN was born at Orange, New Jersey. After graduating at Columbia University he studied at the University of Berlin. John Tyndall fellow in physics at Columbia, 1892–95, he was afterwards professor of physics in the University of Chicago from 1896 until 1914. Prof. Mann acted as special investigator (1914–19) of engineering education for National Engineering Societies, and the Carnegie Foundation for the Advancement of Teaching. Author of several standard works on optics, he has written "The American Spirit in Education" (1919).

Prof. GAMBLE, a Manchester man, was educated there at the Grammar School, and at the University, serving after graduation on its zoological staff for some time. In 1909 he was appointed to the chair of zoology in the University of Birmingham. President of the Zoology Section at the Toronto meeting of the British Association in 1924, he gave an address on "Construction and Control in Animal Life."

Societies and Academies.

LONDON.

Geological Society, June 9.—W. D. **Lang**: *Naos pagoda* (Salter): the type of a new genus of Silurian corals. The detailed structure of the hitherto overlooked species *Ptychophyllum pagoda* Salter is described; it is intermediate between Ptychophyllum and Chonophyllum (in their proper interpretation), and the new generic name Naos is proposed.—J. F. **Jackson**: The junction-bed of the Middle and Upper Lias on the Dorset coast. Deposits of *Harpoceratoides hemera* have been traced throughout the 'Western Cliffs' and a richly-fossiliferous representative of part of the 'transition-bed' of the Midlands has been found at Doghus Cliff. A compact limestone crowded with well-preserved fossils in the marlstone at Thorncombe Beacon appears to be transitional from the sandy clay below the junction-bed, but it is probably a case of pseudo-sequence due to deposition on a sea-bottom of incoherent materials. The strata at Watton Cliff were measured and photographed *in situ*. All the evidence indicates slow accumulation under perfectly tranquil conditions. The massive lithographic limestones contain re-deposited matter, and were formed under much less tranquil conditions.—P. G. H. **Boswell**: A contribution to the geology of the eastern part of the Denbighshire moors. The eastern part of the area, about 72 square miles in extent, between Llanefydd, Denbigh, Ruthin, and the centre of the moors is discussed. The greater part of the area consists of Upper Salopian strata, comprising rocks belonging to the zones of *Monograptus nilssoni*, *M. scanicus*, and *M. tumescens*, but the succession is much obscured by a thick mantle of glacial drift. The sediments are all of shallow-water facies, increasing in coarseness as they become younger, and this is attributed to the filling-up and shallowing of the geosyncline. Tectonically, the area constitutes the north-eastern part of the syncline of the Denbighshire moors, pitching north-eastwards. The dominant faults are of north-and-south trend, but swing north-north-westwards in the northern part, and apparently south-south-westwards south of the district. The structure is interpreted as the result of successive upthrows towards the west, but some lateral movement is probable Numerous cross-faults, usually antedating the north-and-south faults, carve the country into blocks. While much of the faulting is of pre-Carboniferous age and related to the folding, movement on the north-and-south faults was, at least in part, renewed in post-Carboniferous times.

Linnean Society, June 10.—J. G. **Dollman**: Exhibition of a supposed new 'mutation' in the rabbit. The specimen showed the fur thickly interspersed with what appeared at first glance to be 'bristles' an inch or more in length. The 'bristles' were the awns of an Australian grass of the genus Stipa, the fruits of which had implanted themselves in the fur of the rabbit.—I. H. **Burkhill**: Exhibition of Hawaiian volcano plants. Eight mature vascular plants from the surface of one-year-old lava in the crater of Kilauea, Hawaii, three being sedges and five grasses, were found in cracks of the lava-flow of 1924 at places where steam issued. Within the steam-cracks was a mass of the genus Trematodon, its capsules weighted down with condensed water; algæ were observed, as well as a number of sporeling ferns and three small dicotyledons, but none of them were mature enough for identification. On lava three years older isolated plants of *Vaccinium penduliflorum* Gaudich, and *Cyathodes tameiameiæ* Cham existed where steam

being absent, the surface was sheltered by boulders from the perennial north-east trade-wind. But neither of these two species, which seem to be the most xerophytic of the local plants, nor any other broad-leaved plants were observed upon the 1924 lava, which lava alone was hot enough to return rain as steam. The drying is obviously a greater hindrance to encroaching vegetation than the sterility of the lava.—T. A. **Sprague**: The taxonomic position of the Adoxaceæ. The position of Adoxa depends primarily on the interpretation placed on the two perianth whorls, those who regard these as 'calyx and corolla' or 'involucre and corolla' placing the genus near the Caprifoliaceæ, whereas those who regard them as 'involucre and calyx' place it next the Saxifragaceæ or Araliaceæ. The former hypothesis involves fewer assumptions than are required by the other hypothesis, and the evidence from abnormal or rarer types is greatly in its favour. It is suggested that the Adoxaceæ should be placed in Rosales — Saxifragineæ beside Saxifragaceæ. — S. K. **Mukerji**: The vegetation of Kashmir: a contribution to the ecology of the Kashmir Himalayas. Investigation of the plant communities of the Kashmir Himalayas was undertaken during the years 1918–24. Three regions are recognised: the aquatic and marsh vegetation of the Dal Lake of Kashmir; the plant communities of the temperate region of the Kashmir Himalayas (5000-9000 ft.); the sub-Alpine and Alpine vegetation of the Kashmir Himalayas (9000-18 000 ft.).

Physical Society, June 11.—J. H. **Awbery** and Ezer **Griffiths**: The latent heat of fusion of some metals. The method of mixtures was used and refinements were introduced, of which the chief were the use of fairly large charges of metal (of the order of 2 kilograms), and a device by which the hot charge was not allowed in contact with the water of the calorimeter until the latter was completely closed. This device consisted in the provision of a sheet-metal vessel suspended by threads from the main lid of the calorimeter. The aperture through which the charge was introduced was closed by a rotating lid, in the main lid, and the crucible being introduced, was submerged after the closing of this smaller lid by means of a wire passing through an eyelet in the base of the calorimeter, and out at the top.—D. W. **Dye**: The piezo-electric quartz resonator and its equivalent electrical circuit. Such a resonator can be represented by an inductance, a resistance and a capacity all in series. These are pictured as in parallel with another small condenser and the whole is in series with a third condenser, the additional condensers representing air-gaps. The agreement between theory and experiment holds for longitudinal resonators of a frequency so low as 44,000 and for transverse resonators with a frequency up to 15,000,000 periods per second. The temperature coefficient of frequency of a considerable variety of resonators is examined over a range of temperatures up to 40° C.; very diverse results are obtained. The effects of displacement of the resonator from the position of centrality are small but not quite negligible. —Evan J. **Evans**: The current-voltage characteristics of electrostatic machines when supplying current to non-inductive loads and to a Coolidge X-ray tube. A large electrostatic machine was used as a source of potential for the discharge through (*a*) a Coolidge X-ray tube, and (*b*) a non-inductive resistance. In the former case, above a certain critical voltage the discharge is intermittent, while in the latter case the discharge is continuous for all voltages. The intermittence observed is due to the operation of the Pearson-Anson effect, and this implies that the effect of the residual gas in such tubes is not completely insensible above a certain voltage.

DUBLIN.

Royal Irish Academy, June 14.—J. **Doyle**: The ovule of Larix and Pseudotsuga. The ovule of all species of Larix is provided with a large outgrowth on the cone-axis side of the micropilar edge. It is definitely one-sided, and covers the mouth like a hood; the other edge of the slit-like micropilar mouth is unchanged. The outgrowth has a stigmatic function, receiving the pollen and afterwards bending over and in, thus bringing the pollen into the micropilar canal. In Pseudotsuga the micropilar mouth is more slit-like and both edges are differentiated, the cone-axis side being prolonged into a large mass as in the Larix, the scale side forming a second lip very much smaller. Though thus two lipped, it is only the larger one which functions as a pollen-receiving device in a manner strictly similar to Larix. The natural and very close relationship in most characters, except habit, between Larix and Pseudotsuga is again emphasised.

EDINBURGH.

Royal Society, June 21.—W. H. **Lang**: Contributions to the study of the Old Red Sandstone flora of Scotland. (iii.) On *Hostimella* (*Ptilophyton*) *Thomsoni*. A new specimen of the fossil, originally named by Dawson *Ptilophyton Thomsoni*, is described. The investigation of this has shown that the linear bodies are sporangia, enclosing large winged spores. The specimen by which Kidston demonstrated that this fertile tip terminated a frond-like branch-system is described. The genus, Milleria, is founded to include *M. Thomsoni* (Dawson) and *M. pinnata* (Lang) (iv.) On a specimen of Protolepidodendron from the Middle Old Red Sandstone of Caithness. A unique specimen from the Thurso flagstones, which was referred by Kidston to *Protolepidodendron karlsteini*, P. and B., is described; it is the first record of this genus from British rocks. (v.) On the identification of the 'Large Stems' in the Carmyllie beds of the Lower Old Red Sandstone as Nematophyton. The striated incrustations, so common in the Carmyllie beds, have been critically investigated. They prove to have the characteristic structure of Nematophyton, which must have been a very abundant plant at this period. Two types are distinguished, the commoner constituting a new species (*N. caledonicum*), while another, with wider tubes, is compared with *N. Forfarense*, Kidston sp.—S. **Williams**: A critical examination of the Vittarieæ. The genera Vittaria, Monogramma (limited to the Eumonogramme section), Antrophyum, Hecistopteris and Anetium, form a natural group. All are tropical epiphytes with creeping dorsiventral rhizomes. The fronds are simple in outline except in Hecistopteris, where they are dichotomously branched. The venation is typically reticulate, but in some species of Monogramma lateral veins are entirely absent. The central type of stele is the dorsiventral dictyostele. The dermal appendages are always clathrate scales, and the epidermis of the fronds is characterised by the presence of spicule cells. The sporangia are constant in structure throughout the group, and the origin of the sorus is probably always intramarginal. The spore output varies from 32 to 64. The gametophyte, where known, is always divergent from the common cordate type. The prothalli are deeply lobed and multiply rapidly by

vegetative means. From a general survey of the structural characters it is concluded that the Vit... must be placed in any natural classification with the complex of genera containing Adiantu... Cheilanthes, Pellæa, Gymnogramme and Ceratopter...—F. R. Cowper **Reed**: Some new Ordovician and Silurian fossils from Girvan. Two new trilobites, one belonging to a genus (Glaphurus) hitherto known only in America, and some other new forms, are described.—Graham **Kerr**: A gigantic poison fang of a snake obtained from the (?) pleistocene of the Gran Chaco. The name *Bothrodon pridii* has been given to the specimen. The fang measured nearly 65 mm. along the convex side, and has a deep poison-groove along its outer side. The uniform curvature, forming practically a semicircle, suggests that the fang was not adapted for striking but rather for the retention of struggling prey while the poison took effect.—G. Donald **M'Intyre**: Development of the vascular system in the human embryo prior to the establishment of the heart. A detailed account of early stages of vascular formation in some embryos, such as have not been hitherto published, and a summary from the original descriptions of the vessels in a number of young human embryos.—J. M. **Whittaker**: On a polarised light quantum. The refraction and frequency of the light quantum of Sir J. J. Thomson and Prof. Whittaker are discussed analytically, and a modification of it is proposed to explain the phenomena of polarisation.—W. W. **Taylor**: (1) Ferric hydroxide sol and the lyotrope series. The concentration of the univalent salts of potassium which just completely precipitates ferric hydroxide sol in twenty-four hours under strictly comparable conditions has been determined. The order is—acetate, thiocyanate, chloride, bromide, nitrate, iodide, chlorate, the concentrations rising from 0·01 n to 0·083 n. (2) Note on a theory of von Weimarn. According to von Weimarn's theory of the colloid state, the duration of life of a sol is longer when a precipitating ion contains the same element, as the sol. Ferric hydroxide sol is completely precipitated in twenty-four hours by the same concentration of ferricyanide as of the trisulphonates, but the zone of partial precipitation is prolonged. With ferrocyanide the corresponding concentration is the same, and the zone of partial precipitation is also similar; there is in this case, however, at higher concentrations a second zone of precipitation, separated from the first by one of no-precipitation.

PARIS.

Academy of Sciences, May 31.—H. **Deslandres**: The distribution in time of terrestrial magnetic perturbations and the corresponding distribution in the sun of the regions which emit a corpuscular radiation. In an earlier communication it has been suggested that the magnetic storms occur at intervals which are multiples of $R/6$, R being the mean duration of the synodic rotation of the spots. A detailed examination of the data for 1882, 1925 and 1926 is made, and the results exhibited in tabular form; they generally confirm the above view.—Gabriel **Bertrand** and M. **Mâcheboeuf**: The relatively high proportion of nickel and cobalt in the pancreas. It has been shown that animal tissues normally contain minute amounts of nickel and cobalt. The distribution of these metals varies with the nature of the tissue, being lowest in muscle and highest in the liver and pancreas. The original figures were obtained from the ox, but examination of the pancreas from several animals (ox, ... pig) proves that the pancreas is always richest in nickel and cobalt. ... found that preparations of insulin contain several hundred times more nickel and cobalt than the glands from which they are extracted. This raises the question whether these two metals intervene in the remarkable action of insulin, and further work on this is in hand.—H. **Vincent**: The general properties of the cryptotoxins, in particular of tetanus cryptotoxin. The name cryptotoxin has been applied to microbial poisons which, in contact with certain substances, lose entirely under this influence their toxic power, keeping, however, some of their properties, in particular their immunising power. Sodium palmitate has been used as the modifying agent, and this salt rapidly neutralises, *in vitro*, microbial toxins. Experiments with guinea-pigs show that this animal can be injected with tetanotoxin 600 times the fatal dose without inconvenience if the toxin has been previously mixed with a suitable proportion of a solution of sodium palmitate. Similar effects are observed with the toxins of diphtheria, dysentery, typhoid, and *B. œdematiens*. The toxins are not really destroyed, since the sodium palmitate complex treated with hydrochloric acid and filtered from the palmitic acid gives a solution producing, in large doses, symptoms of tetanus in a guinea-pig.—Bertrand **Gambier**: The deformation of a surface with conservation of a conjugated network.—Gaston **Julia**: The conformal representation of areas.—Rolin **Wavre**: The construction of a class of functional automorphs relating to a symmetrical nucleus of Fredholm.—G. **Cerf**: The transformation of certain systems in involution of partial differential equations with two independent variables into an equation of the first order.—E. **Gau**: The transformation of a partial differential equation of the second order into an equation of the first order.—André **Roussel**: An extension of the method of Weierstrass.—**Riabouchinski**: Remarks on the problem of cavitations.—Emile **Belot**: The probable limits of the age of the planetary system, according to the theory of radiation and cosmogonic data.—Mlle. M. **Hanot**: The enlargement by absorption of lines of Balmer's series.—Jean **Dufay**: The spectrum of lightning. A study of the part of the spectrum with wave-lengths less than 3850 Å.U.—C. G. **Bedreag**: The complex structure of the spectrum of copper.—P. **Vaillant**: The passage of the (electric) current in solid salts.—F. **Holweck**: Discussions and recent experiments on the soft X-rays. A discussion of the results obtained by M. Dauvillier and the author.—P. **Lebeau** and A. **Damiens**: Carbon tetrafluoride.—Mme. **Ramart** and Mlle. **Amagat**: Molecular transpositions in the series of the α.α.α.-alkyl-diaryl-ethanols.—René **Souèges**: The embryogeny of the Liliaceæ. The development of the embryo in *Allium ursinum*.—J. **Beauverie**: The cytological bases of the theory of mycoplasma.—G. **Ollivier**: *Thalassoascus Tregoubovi* (new genus, new species), a marine pyrenomycete, parasitic on the Cutleriaceæ.—Théodor **Lippmaa**: Hematocarotinoids and xanthocarotinoids.—A. **Quidor** and Marcel A. **Hérubel**: The simultaneous and monocular perception of two different images of the same object.—Jules **Amar**: Radiations and chlorophyll. The green pigment of leaves holds back the red radiations, the complementary colour, and red rays are most compatible with the persistence of chlorophyll.—P. **Vignon**: The anatomy of the organs of flight in the Phasgonurideæ of the present time and in the Protolocustideæ of the coal measures.—Robert **Weill**: The cnidome of the Trachylideæ (Trachymedusa and Narcomedusa).

Bird Protection in Great Britain.

THE re-introduction to the House of Lords a few days ago of a Bill for the Protection of Wild Birds suggests a glance at some aspects of bird protection in Great Britain. The new Bill proposes to repeal the Statutes, nine in number, extending from 1880 to 1908, which regulate the legal protection of birds in this country, and to replace them by a single body of law more in keeping with present-day notions of bird protection, and in some respects more stringent in its defence of the birds and more exacting in the penalties to be demanded from law-breakers.

This consolidation of bird protection legislation is a welcome move, for the multiplicity, and to some extent confusion, of the old laws militated against their successful working, and unfortunately the need for rigorous protection is still clamant. During the present season we have had the unedifying spectacle of a well-known naturalist and observer being heavily fined for abetting in the taking of clutches, twenty-three eggs in all, of the crossbill in Norfolk. In the Grampians, Mr. Seton Gordon found that the golden eagle's eggs which he had under observation were taken from the eyrie after they had been incubated for nearly five weeks, that is to say, when the chicks were on the point of hatching and the eggs could have been of no value to the collector. These cases are symptomatic of a vast amount of raiding of the nests of the rarer birds which is taken part in and encouraged by unscrupulous collectors who have the audacity to put science in the forefront of their excuses. It is almost impossible, however, for the law unaided to check such misdemeanours. They will be discouraged and arrested only when public opinion makes its voice heard with no uncertainty in the matter.

It is gratifying to know that public opinion is awakening to the realities of the situation and that steps have been and are being taken, by the Government, by municipalities, and by private bodies, which should go a long way to arouse interest in a vast section of the public which has few opportunities of observing Nature at large. To the enthusiasm of Sir Lionel Earle, chairman of the Bird Sanctuaries Committee (England), was largely due the formation of that committee, under H.M. Office of Works, and the institution, following on the report of the committee issued in 1922, of bird sanctuaries in the Royal Parks in London. The report for 1925, just issued, shows that the sanctuaries continue to give great encouragement to bird life, and that efforts are continually being made, by increasing the amenity of the reserves from the birds' point of view, to encourage the influx of greater numbers and greater variety of wild birds. Supplementary reports dealing

with the sanctuaries at Hyde Park, Kensington Gardens, Richmond Park, Bushey Park, Greenwich Park, St. James's and Green Park show not only that the reserves were largely used as resting-places by birds on migration, but also that a very considerable variety of wild birds took up their summer residence there. At least 18 species nested in Hyde Park and Kensington Gardens, 47 in Bushey Park, and 55 in Richmond Park.

There can be no doubt that a great part of the success of a small sanctuary depends upon the selection of the proper vegetation, and that the steps taken by the Bird Sanctuaries Committee, with the view of offering an attractive food supply to winter migrants, and suitable shelter for summer residents, have done much to ensure the increasing success of the sanctuaries in the Royal Parks. These steps include the planting of berry-bearing trees and of suitable nesting bushes for summer residents, the thinning out of plantations in order that wild flowers, such as foxgloves, willow-herb, and thistles, may grow and seed, and the sowing of teazles, a winter food particularly favoured by goldfinches.

In Scotland, similar steps have been taken in the Royal Park of Holyrood, where Duddingston Loch with its extensive reed-beds, a much-frequented winter haunt of immigrant ducks, promises to become a reserve of outstanding interest. During the present season, it is recorded by Mr. Kirke Nash that the common pochard, which has not hitherto been known to nest in Midlothian, has reared two broods on the Loch.

In several cases city corporations have taken part in the sanctuary movement, the lead having been taken in Scotland by Glasgow, which has created bird reserves, with feeding-tables and so on, in its public parks. The movement is well fitted to stimulate public interest, for it affords new and hitherto unattainable opportunities to town-dwellers for the observation, if not of nests and eggs, at any rate of adult and young birds at the most interesting stage of their existence. Furthermore, it places before the minds of all and sundry, with steady insistence, the facts that birds have an interest and afford pleasure, and that they require protection. The extension of the municipal formation of bird sanctuaries in public parks is a movement worthy of every encouragement because of its possibilities in moulding a wide appreciation of living things; but it must be recognised that such steps can have no bearing on the pressing question of the protection of the rarer birds which are threatened by the attention of the collector.

For the progress made, no body deserves more credit than the Royal Society for the Protection of Birds. The annual report of this influential society indicates the part taken by the Society's watchers in ensuring the safe breeding in certain localities of some of the rarer birds, such as choughs, Kentish plover, Norfolk plover, Dartford warbler, phalaropes, and others. It points out to how great a degree the extension of motor traffic, the breaking up of great estates, and expansive building, are gradually obliterating woods, parks, and meadows, and spreading disturbance in the countryside. In the result, the homes, haunts, and food supplies of wild birds are being altered, and a steady change is taking place in the character, though not in the numbers, of the bird population. It points out that the destruction of sea-birds caused by the deposition of oil at sea, either as waste from oil-driven ships or as cleanings of tankers, is a problem that still seems far from solution, in spite of the three-mile limit imposed upon such discharge by law. But several nations have taken up this matter with energy, and sooner or later some means may be found through international action of avoiding needless destruction.

The report states that afforestation, which had become an imperial necessity, gave many a qualm to the lover of natural woodlands not planted for profit or grown for the axe. In this connexion, the Government could not do better than emulate the action of the various States of Australia, which automatically convert forests under the charge of Government departments into wild animal reserves. Were similar measures taken in Great Britain with regard to the Government afforestation areas under the control of the Forestry Department, a first and important step would be made towards the protection of the rarer birds and beasts, and towards the realisation of that national park which Britain alone amongst the great nations still lacks.

JAMES RITCHIE.

Physiological Optics and Psychology.

Helmholtz's Treatise on Physiological Optics. Translated from the third German edition. Edited by Prof. James P. C. Southall. Vol. 3: *The Perceptions of Vision.* Pp. xi + 736 + 6 plates. (Ithaca, N.Y.: Secretary, Optical Society of America, Rockefeller Hall, 1925.) 7 dollars.

"To the solid ground
Of Nature trusts the mind which builds for aye."
—WORDSWORTH.

THE issue of this volume completes a great task. The English-speaking public has now at its disposal for the first time an edition in English of the epoch-making work of von Helmholtz as it originally appeared, along with the new material which was included in the third German edition to bring the work up-to-date, and some additional matter specially

included in the American edition. In the present volume, this additional matter, contained in two notes by von Kries, one on the perception of depth, the other on visual rivalry, is less in amount than the corresponding matter in the first two volumes. But the whole volume is considerably larger than either of the others, and about one-third of it is occupied by the notes and the appendix contributed by von Kries, on almost every branch of the subject dealt with, which were added to the third German edition of the text. The notes appear at the ends of the several divisions of the subject, and the appendix is given at the end of the volume. It deals with the nature of the idea of space in general, the relations of normal localisation, localisation and anomalous eye adjustment, learning to see, and forgetting, the physiological foundations of judgment and learning, empiricism and nativism or intuitionalism, the origin of the laws of the ocular movements, historical and critical comments, and the theory of binocular instruments.

The whole subject of physiological optics involves physical, physiological, and psychological questions. The present volume deals specially with the latter and the phenomena which give rise to them. In this department, as in the other two which were specially treated in the first and second volumes, Helmholtz was a pioneer. Much time has elapsed since he wrote his discussion; and it might be expected that much, perhaps radical, change of view may have taken place especially where opposing theories were concerned. Helmholtz realised his position clearly. "It ought to be said in the beginning," he remarks, "that our knowledge of the relevant phenomena is still too limited to justify us in acceptance of any one theory to the exclusion of all the others." "I acknowledge that we are still far from a real scientific comprehension of psychic phenomena." "I frankly admit, however, that these questions under discussion are not altogether ready for final decision. My own attitude to them is due partly to the simplicity of the explanations that are afforded in this way, but especially to systematic considerations also; for I think it always advisable to explain natural processes on the *least* possible number of hypotheses and on those which are as *definitely formulated* as possible." Here we have Helmholtz's creed, which we have already recognised (NATURE, vol. 114, p. 887, vol. 116, p. 88) in rigid application in the physical and the physiological tracts of the subject, carried over scrupulously into the less well-charted psychical region—simple postulation, simple formulation, simple explanation, appeal to facts. "To the solid ground of Nature trusts the mind which builds for aye."

In accordance with this undeviating search for truth as tested by its outstanding characteristics, in accordance with this systematic presentation of it in a form of statement the most easily testable, is there also to be found, in this volume as in the other two, the impress of the hall-mark of time, stamping it as the enduring creation of genius? In answer we need only select, almost at random, words of von Kries, the writer of the notes and the appendix which review and estimate the further advance of the subject during half a century. He takes, in one respect at least, a line of thought differing from that of Helmholtz, but his words are such as these.

"Helmholtz's classical work, published more than forty years ago, was based partly on philosophical considerations, partly on comparatively simple results of direct self-observation, and, partly too, it should be added, on a vast amount of empirical observation in the ordinary sense. But even in this latter respect, in spite of many new facts that have been gleaned and some corrections that have to be made here and there, the material contained in the first edition of the 'Physiological Optics' may still be said to be essentially correct and pertinent."

"Those points in regard to localisation where we have been obliged to differ from Helmholtz (or rather, strictly speaking, where it was found necessary to develop his theory further) are only of secondary importance after all, no matter how much weight may be attached to them."

"It would be therefore a complete misapprehension of Helmholtz's views (as has been intimated sometimes) that he meant to deny altogether the participation of innate factors in the case of localisation. The truth is, rather, that Helmholtz was disposed to think that from his point of view it was extremely probable that there was some kind of co-operation such as we have deemed likely; that is, with respect to the relationship existing between the visual direction and the location on the retina, although he doubted whether such an assumption could be absolutely verified. The fact that modern investigations of strabismus have enabled us to develop still further assumptions of this sort need not imply that any fundamental modification has been made in Helmholtz's theory."

"The main thing to be remembered is that to a great extent these modern investigations have *corroborated* in a very positive manner inferences that Helmholtz had already made from the scant material at his disposal at that time. The main conclusions which he reached have been shown to be absolutely probable."

"The facts tend to support the fundamental conceptions of an empirical theory to a remarkable degree, although perhaps not altogether to the extent that Helmholtz supposed. It would be turning things upside down, it seems to me, to regard these new facts as a corroboration of the points of view of the intuition theory. They are certainly the opposite of what might be anticipated on the basis of those conceptions."

"After all, naturally disposed as I am to agree with many of my *confrères* and to regard learning as being a physiological process, I never have been able to consider this as amounting to any profound or fundamental divergence from Helmholtz's views."

"Helmholtz was absolutely right in disputing the very principle on which the whole nativist conception was based."

"It was stated at the outset (and the fact has been brought out still more clearly in the course of this discussion) that it would be a mistake to think of nativism and empiricism as two mutually antagonistic conceptions involving a choice one way or the other. Experience is placed in the foreground in the empirical theory, and innately determined relations in the intuition theory; and undoubtedly (speaking perfectly generally) both of these things have something to do with our perceptions of space. Here, if anywhere, it will be true that there is a certain amount of justification for each of the two originally conflicting opinions, according to the degree of importance that was attached to one or the other of these things."

"Any one who will follow the argument as here presented will see that the principle which has guided us, and which remains still to-day the best way of obtaining an insight into those problems and is the basis of future investigation, has been the empiricism of Helmholtz, even though it has had to be modified and amplified in many respects."

In the development of any scientific subject, fundamentally unprovable postulates have to be made. In the present case these are the postulates of the innateness of certain ideas or intuitions. The aim in all sciences is to reduce these to a minimum, and Helmholtz, in his development of the subject, strove to push the unexplained intuitional basis as far back as possible. There are three ways in which the expression of conditions may be made in regard to vision: the physical, the physiological, and the psychical. Each of these is equally fundamental and contributive. Each, if the interconnexions were given, is equally valid and available for the expression of the ultimate laws and explanations. Yet Helmholtz's use of the psychological mode of description of the phenomena, for example, especially in regard to phenomena of colour contrast, has been decried as a subterfuge and an error. "The more attentively I have studied the phenomena," he says, "the more I have been impressed by the uniformity and harmony everywhere of the interplay of the psychic processes, and the more consistent and coherent this whole region of phenomena has appeared to me." The whole of his psychic treatment of the phenomena of colour contrast, far removed from the exclusion of future development, can be expressed in mathematical symbols and equations involving the external stimuli and the threshold values which sum up the effects of the internal physical, physiological, and psychic activities.

No mistake is made by von Kries in this connexion. He says: "Some brief allusion may be made to the utter inaptness of an opinion which is sometimes expressed, namely, that, since Helmholtz's views were *psychological*, they had put an end to all further investigation." "In fact we owe it to the 'empiricists' and not to the 'nativists,' that a new and fruitful line of inquiry has been started by studying strabismic vision, for instance." "On the other hand, the feature of the nativist systems that aroused Helmholtz's special opposition must also be pronounced unsound and untenable at present."

Recognition should be made of the unusually fair and careful way in which von Kries states his own views when they differ from those of von Helmholtz. He has attained to that absolute impartiality which is so difficult to reach even in scientific discussion. Alike in judicial fairness, in acuteness of perception, and in concise clearness of expression, his work is worthy of its place alongside that of the master.

The editor of this edition, along with his band of able co-workers, are to be congratulated on the completion of the task of translation. Resting from their labour, they can await the award. For the issue of this edition cannot fail to have its influence on future work in the field with which it deals. It is fitting that its home should be in America, for a strong group of the workers dwells there; but it should, and will, go out into all the world.

W. PEDDIE.

The Future of America.

(1) *Midas: or, The United States and the Future.* By C. H. Bretherton. (To-day and To-morrow Series.) Pp. 96. (London: Kegan Paul and Co., Ltd.; New York: E. P. Dutton and Co., 1926.) 2*s.* 6*d.* net.

(2) *Atlantis: America and the Future.* By Colonel J. F. C. Fuller. (To-day and To-morrow Series.) Pp. 96. (London: Kegan Paul and Co., Ltd.; New York: E. P. Dutton and Co.; n.d.) 2*s.* 6*d.* net.

THESE two small books on a great subject are included in the "To-day and To-morrow" series, designed by the publishers to provide a stimulating survey of the most modern thought in many departments of life. Both are accordingly written in a critical and provocative style, compact with aphorisms. America's place in the world is assured and no resentment will be felt there at attempts to discover chinks in her formidable armour. Of the two books, Mr. Bretherton's is the longer and more careful study. Colonel Fuller's suggests the rapid travel impressions of a writer possessing a mature knowledge of world-history.

What is the basis for the strong and not altogether comfortable feeling that America is destined to exercise a powerful influence on the future of the world? The American, "the new white man," marches round the world with his war drum and the European falls in behind "with many a backward glance at the good old days." Nevertheless, the achievements of the United States in art, literature and science are unimportant in relation to their wealth and population. Jazz music and the skyscraper are "the only two new art forms" which Mr. Bretherton is prepared to concede to America as contributions to civilisation. As to their education, the United States, he says, have countless universities but no educated class "outside of their college professors, who rank in the social scale a little higher than the average preacher, and a little lower than the average bootlegger." The matter can be tested by the output of books. "More books on natural history, botany and country life generally are published every year in England than have been published in the United States since the *Mayflower* landed there. The same is true of almost every other branch of literature outside of fiction."

As to forms of government, were we not given to understand that America wished to make the world safe for democracy? Mr. Bretherton produces no evidence of any genuine enthusiasm for democracy. Professional politicians, fanatics with a mania for inhibitions, bosses and spellbinders pullulate. The American reacts by forming the habit of acting, thinking, living and believing 'by numbers.' Prohibition, it is well known, does not prevent an American from getting a drink. But this necessitates a mental process. "He will in the end decide that it is simpler (and more profitable) to stay dry and reserve his mental processes for money-making." So with Fundamentalism. The vast majority of American people, Mr. Bretherton asserts, are reconciled to evolution and have no quarrel with science, which scatters machines and fertilisers with a fatherly hand. Fundamentalism will 'win through' because big business will decide that the man-machine who pauses intermittently from wielding his shovel to ask himself unanswerable questions about the macrocosm is a shade less efficient—say by one-tenth per cent.—than if he accepted "the Bible as written." "The most striking thing about the young Americans of to-day," says Mr. Bretherton, "is that they know nothing and have no ideas of their own." They are forgetting how to think. Like goldfish, they chase feverishly round a glass globe, seeming in some mysterious way to be unaware of one dimension. Their industry is amazing, whether in money-making or in ticking off the sights of Europe in Baedeker.

Significantly, neither author attempts a chapter on American humour, perhaps because it would have resembled the famous chapter on snakes in Ireland. The discussion of the American woman seems inadequate to the importance of the subject. Mr. Bretherton regrets her limited output of poetry, fiction and ephemeral literature. Colonel Fuller is captivated by her charms, contrasting her favourably with her brothers, who appeared to him "gross, ill-mannered, and in their straw hats and trouser belts more or less offensive to the eye."

The question obtrudes—How will it all end? It would be unfair to the authors to reveal their conclusions. Both recognise that something will happen some day when America is disillusioned about the power of money and the booster's curve approaches horizontality, its tangent vanishing like the Cheshire cat. The fate of Rome is not reserved for America, for the simple reason that there are no barbarians to rush in and submerge the American counting house and lobster palace "in one red burial blent." Authors who attempt to foretell the future of America in a hundred years are on safer ground than men of science who predict the position of an unknown planet or the properties of an undiscovered element. Their work should be encouraged, for the national tendencies which they explore have their bearing on our daily life. Possibly the jazz music wafted across the Atlantic sounds a clarion bugle-call if we would listen and interpret.

T. LL. H.

Colloid Chemistry.

(1) *Das kolloide Gold.* Von R. Zsigmondy und P. A. Thiessen. (Kolloidforschung in Einzeldarstellungen, Band 1.) Pp. x + 229. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1925.) 14 gold marks.

(2) *Das kolloide Gold in Biologie und Medizin: die Goldsolreaktion in Liquor Cerebrospinalis.* Von Dr. Ernst Joel. (Kolloidforschung in Einzeldarstellungen, Band 2.) Pp. viii + 115. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1925.) 7·50 gold marks.

(3) *Einführung in die Chemie der polymeren Kohlenhydrate: ein Grundriss der Chemie, der Stärke, des Glykogens, der Zellulose und anderer Polysaccharide.* Von Prof. P. Karrer. (Kolloidforschung in Einzeldarstellungen, Band 3.) Pp. ix + 295. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1925.) 7·50 gold marks.

(1) THIS is the first of a new series of monographs on colloid chemistry, and the preface, signed by Prof. Zsigmondy alone, serves as a general introduction of the enterprise. The distinguished author deals somewhat severely with certain tendencies which

he discerns in the rapid development of the discipline during the last twenty years; the failure of authors to maintain the standard expected from workers in the field of exact science; a preference for philosophical treatment and undue generalisation; neglect of the chemical nature of the systems investigated, and other shortcomings. Against these has to be set much exact work carried out by isolated investigators, and the object of the series is to collect and co-ordinate such work and to make it generally accessible.

The first volume may certainly be said to have achieved this object; it contains everything worth knowing about gold sols. The methods of preparing them, which are due to the author, are described in every detail, and the necessity of strict adherence to these directions is duly emphasised. Their electrical and optical properties are then treated exhaustively, as well as a number of phenomena which, while not specific to gold sols, have been largely studied on this material; such are coagulation velocity and protection. The chemical composition of the sols is also discussed at length, and the author produces ample evidence to show that stable sols need not contain oxygen; a result which contradicts the view held—at least at one time—by Pauli and his school, that 'aurate' complexes impart the negative charge to the gold particles.

The volume illustrates the important part played by the study of gold sols in the development of modern colloid physics and chemistry. That this study leaves untouched some of the most important and difficult problems in this field, such as viscosity and solvation, is worth pointing out to students who are invariably attracted by the ease with which gold sols—of sorts—can be made and by their somewhat spectacular properties.

(2) Dr. Ernst Joel's volume deals with a highly specialised application of gold sol: the Lange method of diagnosing luetic and meningitic infection in the cerebro-spinal fluid. The protective effects of these morbid fluids differ from that of the normal and from one another, so that they can be distinguished by coagulating gold sol with sodium chloride in the presence of the fluid, of course in strictly defined ratios and conditions. By way of introduction the author gives a lucid and detailed account of the phenomena of protection by proteins and protein mixtures, and of the related phenomenon of sensitisation of these bodies. Critical application of this vast and difficult evidence to the Lange reaction seems to lead to the conclusion that the essence of the difference in the three types of fluid is a shifting of the albumin-globulin ratio.

(3) Although the eminently colloidal character of the polymerised carbohydrates has never been in doubt, their systematic study by modern methods has, until recently, lagged far behind that of the proteins. Some impetus has no doubt been given to it during the last decade by the enormously increased importance of cellulose and its esters in the arts of peace and war. The volume under review deals very exhaustively with starch, glycogen and cellulose; other carbohydrates receive briefer but adequate mention. The point of view is largely that of the organic chemist, structural formulæ being discussed at great length; the aspects which particularly interest the colloid chemist, such as apparent molecular or 'micellar' weights, are, however, not neglected. He will, at any rate, find here ample information regarding the chemical character of his materials which will enable him to approach one of the great tasks of the future—the co-ordination of colloidal properties with chemical constitution.

All three volumes are excellently printed and well bound, and the student of colloids who wishes to keep his library complete will have to face the purchase of these and of subsequent monographs in the series.

Aspects of the Oceans.

A Study of the Oceans. By Prof. James Johnstone. Pp. viii+215. (London: Edward Arnold and Co., 1926.) 10*s.* 6*d.* net.

LIVERPOOL is distinguished amongst British universities by the possession of a chair of oceanography from which Prof. Johnstone speaks as an exponent of the science. The subject naturally appeals most strongly to a seafaring people in those practical aspects which affect navigation, cable-laying, fisheries and the like; but Prof. Johnstone very wisely takes a wider view in opening out vistas of geological evolution and historical discovery. These considerations, rightly balanced, should serve to place the subject on a wide academic basis. The exact purpose of the book before us is not stated, but the seven chapters read like a series of semi-popular lectures each so far complete in itself as to involve a certain amount of repetition, not unhelpful to students though detracting in some degree from the close-knit unity which one looks for in a scientific treatise.

The elements of the book are rather difficult to blend. The first chapter deals with an advanced modern problem, the geological history of the oceans, and the next two with the speculations of the ancient Greeks and the history of nautical discovery since the time when the Mediterranean was 'The Great Sea.' The four remaining chapters deal from both points of view with the circumpolar regions, the Atlantic, the Pacific and the Indian Oceans respectively. The difficulty of

developing such a plan is obvious. It might have furnished a satisfactory course of University Extension lectures delivered with the animation of an enthusiast to an eager audience, and some passages (*e.g.* p. 122) suggest that, like Huxley's "Physiography," the book owes its literary form to notes taken from extempore speaking. If, however, the object was not to stimulate general interest but to guide serious study, a more systematic treatment and more sedulous revision would have done fuller justice to the author's wide knowledge.

No one can bring a great subject within the compass of a small book without leaving out much which is really of importance. Hence an author should not be taxed with omissions which he probably recognises and regrets; still, it is surprising to find that even so brief a history of the oceans as this could be written without mentioning the name of Maury. The publication of Maury's "Physical Geography of the Sea," in 1855, seems to many of us to have been the launch of the modern science of oceanography, and the memory of the great American sailor deserves to be kept alive.

I confess that I do not know enough of geology or ancient history to pass an opinion on the exposition of these subjects, but I do venture to question Prof. Johnstone's subdivision of the oceanic depression (p. 11) into *Continental Shelf* and *Ocean Bed* with the boundary between the two taken as the line of 1000 fathoms. If room could have been found for a notice of the hypsographic curve, the advantage of a more detailed subdivision of the ocean floor and slopes would probably be recognised. Even granting that the 1000 fathom isobath is to be taken as a physical boundary, it is unfair to give to the region on its landward side the name of the Continental Shelf. Most other oceanographers have accepted that term as meaning the gently sloping zone covered by shallow water extending from low-water mark to a depth of about 100 fathoms, or in rare cases, as on the Antarctic coasts, to 200 or 300 fathoms. It corresponds to the old nautical 'in soundings,' and at its deeper end there is always a sudden increase in the gradient of the Continental Slope which leads to the ocean depths. When I introduced the term in 1888, I was impressed by the wide flat expanse of the Vidal Bank west of Scotland, and recognised that it was not a local but a world-wide feature of the transitional area between land and the deep sea. Prof. Johnstone has no doubt excellent reasons for departing from the international nomenclature settled for the great Monaco bathymetrical chart, and he may have stated them in some work with which I am not familiar. It would, however, have saved confusion and perhaps perplexity if he had chosen for this zone covered with water from 0 to 1000 fathoms deep, a name which was not already in use for a definite and restricted portion of the area which he includes within it.

The book has the advantage of a good index and a brief bibliography, which might well have been supplemented by reference to the foreign literature of the subject.

HUGH ROBERT MILL.

Our Bookshelf.

Ancient Greece at Work: an Economic History of Greece from the Homeric Period to the Roman Conquest. By Prof. Gustave Glotz. Translated by M. R. Dobie. (The History of Civilisation Series.) Pp. xii+402. (London: Kegan Paul and Co., Ltd.; New York: Alfred A. Knopf, 1926.) 16*s.* net.

IN "Ægean Civilisation," a previous volume in this series, Prof. Glotz traced Mediterranean culture from its beginnings to its culmination in Minoan Crete and its decline on the mainland. To present as complete a picture as possible he sketched such an outline of the social organisation of these early periods as may be deduced from archæological remains, eked out with evidence from other sources. In the present volume he takes up the social and economic story of Greece at the point where the previous volume ended. Beginning with the pastoral society of Homeric times, he traces the development of social and economic organisation through the archaic period, the predominance of Athens, and Hellenistic times. Each period has its peculiar characteristic and, as he points out, no general statement is applicable to Greek economics as a whole, but only with special reference to some one of these periods.

Those who are not already familiar with the data will probably be surprised at the amount of information Prof. Glotz has been able to gather together relating to the early Homeric period. The manner in which he extracts his material from incidental references and allusions in the Iliad and Odyssey commands our sincere admiration. At the same time, his deductions are capable of being checked by comparison with what we know of pastoral societies elsewhere which are organised in groups similar to the Greek *gene.* The archaic period, notwithstanding that evidence of a more direct character is available, is really more obscure. The treatment of the period of the Athenian hegemony is illuminating. It is, of course, recognised that slavery is the essential factor in the social and economic organisation, but it is especially in relation to the position of the metics that Prof. Glotz is most suggestive. Is it not possible that the influence of this element in the population in the subsequent development of the characteristics of the Greek people has been underrated?

The Chemistry of Drying Oils. By Dr. R. S. Morrell and H. R. Wood. (Oil and Colour Chemistry Monographs.) Pp. 224. (London: Ernest Benn, Ltd., 1925.) 21*s.* net.

CHEMICAL industry has become so highly specialised that at the present day it is practically impossible for one person to write from first-hand knowledge a trustworthy text completely covering even one industry. It is only by a series of monographs continually being

brought up-to-date and written by experts with direct knowledge of particular processes that detailed information of real value can be secured. Under the editorship of Dr. Morrell we have an example of such a series of monographs for the oil and colour industry of which the volume under notice forms a part.

The expression and extraction of linseed and other less known oils from their seeds, the refining and bleaching of these oils as well as the preparation of boiled, blown and stand oils, receive detailed treatment. The use of these oils in the manufacture of linoleum and patent leather and the employment of drying oils as electrical insulators receive detailed consideration. The aim has been to give a trustworthy account of the most recent information regarding various processes and methods, with a critical survey of the literature by works' experts. Notwithstanding the bias towards the industrial aspect, stress has been laid by the authors on the importance of physical properties in relation to chemical changes. The composition of drying oils and their component acids, with the chemical changes occurring on drying, have been exhaustively treated before discussing manufacturing details. A valuable addition is the good list of references at the end of each chapter.

The book is excellently produced, and in fact for a monograph that will require frequent editions to keep abreast of practice, the finish is, if anything, too durable. The high price of this book, with only 200 pages of text, makes such a remark pertinent. J. REILLY.

Three Men Discuss Relativity. By J. W. N. Sullivan. Pp. xxx+233. (London and Glasgow: W. Collins, Sons and Co., Ltd., 1925.) 7*s.* 6*d.* net.

MR. SULLIVAN has achieved something new in the exposition of relativity by writing in dialogue form. One is inevitably reminded of Galileo, but in Mr. Sullivan's book, unlike that of the great Florentine, the characters are not provided with conflicting preconceptions. They are, in fact, not private individuals so much as actors whose parts are made to fit together in such a way as to provide a smooth, uninterrupted account of the theory for the reader. After a brief introduction, six dialogues are set forth, between a mathematical physicist, a philosopher, and an ordinary intelligent person. The mathematical physicist has undertaken to expound the theory of relativity to his companions, who make just the right remarks or ask appropriate questions at frequent intervals. It must be confessed that the ordinary intelligent person is much more intelligent than the sort of person one ordinarily meets with.

From an artistic point of view, the dialogue method as here employed can scarcely be regarded as successful. It does, however, add considerably to the interest of the exposition, and is on that ground justified. The mathematical detail of the subject is almost completely excluded from the dialogues and given in a 45-page summary at the end. Those who wish to obtain an accurate idea of relativity in rather more than its outline and are prepared to expend some mental effort, can do no better than read this agreeable and well-produced volume. "My own indebtedness," writes the author, "is chiefly to Prof. Eddington's 'Mathematical Theory of Relativity.' It is easily the best exposition I have read, and I have adhered to it almost slavishly in the following pages." It will be gathered that the treatment is not wholly original, but the book is not a superfluous paraphrase of Eddington's work.

The Geology of the Netherlands East Indies: Lectures delivered as Exchange-Professor at the University of Michigan in 1921–1922. By Prof. H. Albert Brouwer. Recorded and prepared by Laurence M. Gould. (University of Michigan Studies, Scientific Series, Vol. 3.) Pp. xii+160+18 plates. (New York: The Macmillan Co., 1925.) 3 dollars.

THE thanks of all students of geology are due to Prof. Brouwer and to the University of Michigan authorities for this very readable and well-illustrated digest of our present knowledge of East Indian geology; the more so because a large proportion of the extensive literature published on the subject during the last few years has appeared in Dutch.

Of especial interest are those chapters dealing with the tectonic and volcanic features of the region, and their bearing on modern theories of Alpine structure. The author explains how the configuration of a large part of the Archipelago—in particular the two festoons of islands which surround the Banda Sea—is a direct expression of mountain-building processes still in operation. The foreland is formed by the Australian continent and the bordering Sunda shelf; the rising festoons are actual geanticlines, and the deep, elongated sea-basins between them true geosynclines; the younger arc (the inner one) is characterised by active volcanicity, which is absent in the older one. If the compressive forces now in operation persist, a continental mountain range of the Alpine type may ultimately develop.

Higher Mathematics: for Students of Engineering and Science. By Frederick G. W. Brown. Pp. xii+488. (London: Macmillan and Co., Ltd., 1926.) 10*s.*

THIS work embodies those branches of pure mathematics required by senior engineering students up to degree standard and it covers the field very adequately. There are chapters on determinants, spherical trigonometry, several chapters on differentiation and integration and ordinary differential equations up to simultaneous systems, plane curves and three dimensional geometry. For an attempt to return from the monograph to the 'comprehensive' type of book it is eminently successful, and the numerous examples are well chosen with the correct practical bias. The theoretical parts are weaker in presentation than the practical portion, but not sufficient to vitiate a really useful book.

Wolfram: Fortschritte in der Herstellung und Anwendung in den letzten Jahren. Von Dr. Hans Alterthum. (Sammlung Vieweg, Heft 77.) Pp. viii+111. (Braunschweig: Friedr. Vieweg und Sohn A.-G., 1925.) 4·50 gold marks.

THIS useful monograph contains an account of the newer researches on tungsten, its alloys and more important compounds, made since 1910, and is not a complete account of the subject. The localities of the occurrence of tungsten ores, the preparation of tungsten and the physical properties of the metal, together with analytical information and some account of the compounds, are dealt with. There is no index.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Solidification of Helium.

ON June 25 helium was compressed in a narrow brass tube forming communication between two German silver tubes. The brass tube and part of the two German silver tubes were in a liquid helium bath. At a pressure of 130 atmospheres the tube system appeared to be blocked. When the pressure was diminished by 1 or 2 atmospheres the tube system was open. The temperature of this experiment was somewhat uncertain. By diminishing the pressure of the liquid helium bath the same phenomenon was observed at a temperature of about 3·2° K. at 86 atmos., and at a temperature of about 2·2° K. at 50 atmos. From the regularity of the phenomenon it appears that we were observing the solidification curve of helium. This method of observing solidification has indeed already been used by Kamerlingh Onnes and Van Gulik in preliminary measurements on the curve of solidification of hydrogen.

A repetition of the experiment on July 1 confirmed the early observations. At 4·2° K. helium solidified at 140 atmos. The solidification curve was prolonged to 1·1° K., and the helium solidified then at 26 atmos. The exact numerical data will be given elsewhere. The solidification curve bends so that at the lower temperatures it shows a tendency to become parallel to the axis of the temperatures. So far as can be ascertained from these observations, helium is expected not to have a solid-liquid-gas triple point.

Finally, helium was compressed in a glass tube provided with a magnetic stirrer after the pattern of Kuenen. The observations on the solidification of helium were confirmed. The stirrer was seen to stick when the helium solidified. In one experiment part of the substance was liquid and part solid. One could hammer the solid block with the stirrer that was in the liquid part. A limiting surface between the solid and the liquid could not, however, be seen. Solid helium forms a homogeneous transparent mass, the refractive index of which probably differs extremely little from that of the liquid.

W. H. KEESOM.

University of Leyden.

Supplementary Note on Radiation.

PERMIT me to make a little correction to my letter on page 801 (June 26) about the law of radiation. It is usual to quote Rayleigh's law in the form there given, namely, $8\pi RT\lambda^{-4}$; the $8\pi R$ part is, however, due not to Rayleigh but to Dr. Jeans (see *Phil. Mag.* for July 1905). In Rayleigh's 1900 paper he left the constant undetermined. Afterwards, in NATURE for May 18, 1905, he concluded, from simple gas-theory, that the constant would be $64\pi R$; but Jeans speedily pointed out a source of error, and made the constant $8\pi R$, a correction which Rayleigh at once accepted (see his "Collected Works," vol. 5, p. 253; also p. 248).

It is interesting to note that had the possible modes of vibration been one-dimensional, as in sound, the numerical part would have been 4π; in light the transverse vibrations have two modes open to them. This makes the constant 8π; while if, as in an elastic solid, vibrations had been possible in all three directions of space, the constant would have been 12π (see Jeans's "Report," p. 14). In no case could it be 64π; but that was a slip, due to counting some integers twice over.

Another point in which my letter might be misleading is that the dynamical proof of the continuous-spectrum law of radiation had given no indication that the result would only be true for long waves. It must have been clear by common sense that it did not hold for short waves, but no reason for this was suggested by orthodox dynamics. The serious discrepancy remained a puzzle, until it was solved by the quantum.

In other words, as I express it, neither gas-theory, probability, nor dynamics was competent to express fully the interaction between matter and ether. An expression obtained by attending to continuous equipartition of energy in matter alone, was bound to be incomplete; while if the doctrine of continuous equipartition was extended to the ether, with its apparently unlimited degrees of freedom, the result was impossible. Indeed, thirty years previously, Maxwell had emphasised this outstanding difficulty of molecular theory, in his lecture on the "Molecular Constitution of Bodies," reported in NATURE, vol. 11, pp. 375-6 (or "Scientific Papers," vol. 2, pp. 433-438), and had decided that whatever the constitution of the ether might be it could not be molecular. Discontinuous partition, as represented, by the quantum, enabled the true radiation law to be obtained; and the puzzle was thereby shifted to an explanation of the quantum itself—a problem which can scarcely be solved until we possess more knowledge about the intimate structure of the ether.

OLIVER LODGE.

Prof. Miller's Ether Drift Experiments.

THROUGH the courtesy of Prof. Miller I have been made acquainted with the results of his February series of observations made on Mt. Wilson, to be published in the *Proc. Nat. Acad. Sci.*, Washington. I am sorry to say that my opinion concerning the significance of the observed displacements disagrees with his so completely that I cannot attribute the effect to any cosmic cause.

The calculations of Prof. Miller and his collaborators lead to the conclusion that an ether drift directed towards a point in the constellation Draco (R.A. 17 h., Decl. +68°) would agree best with the observed effects. The drift is assumed to be caused by a motion of the solar system towards the given direction with a velocity of approximately 200 km./sec. A partial drag of the ether is supposed to reduce this velocity to 10 km./sec. at the surface of the earth, thereby annulling the influence of the orbital motion.

My objections against these assumptions are laid down in a paper published recently in the *Zeitschrift fur Physik* (vol. 35, p. 723, 1926). The theoretical curves of the line displacements as plotted against the azimuth of the apparatus are given there for different directions of the ether drift. A comparison with the mean value of Prof. Miller's observations shows systematic deviations as large as the full amount of the effect occurring at certain hours of the day. The asserted good agreement between the assumed ether drift and the observations is due to the fact that Prof. Miller has arbitrarily displaced the theoretical curves, giving the azimuth of drift as a function of sidereal time to match the empirical curves. This procedure may be justified in all cases where only the *shape* of the curves is essential. In the present case, however, the absolute values of the curves play a fundamental rôle.

As Prof. Miller rightly remarks, the projection of a

fixed direction in space on the horizontal plane ought to move equally to the east and to the west during a sidereal day. What actually happens is the occurrence of an effect pointing towards the north-west quadrant of the compass in about ninety-five per cent. of all observations. This fact seems to be fatal to the assumption of an ether drift of constant direction towards a certain point of the heavens. If the effect were really genuine it would prove the existence of a north-west drift of the ether accompanying the earth's rotation. The velocity of the drift would be at least 10 km./sec., whereas the velocity of the daily motion of a point of the equator is only about five per cent. of this amount. The advocates of the ether will find it difficult to account for a whirling motion of the ether round the earth with a velocity surpassing that of the earth's rotational motion about twenty times.

Apart from the systematic deviations, there are large irregular discrepancies in the observations. The mean value of the ether velocity at a certain hour of the sidereal day taken from twenty single observations differs sometimes by more than 100 per cent. from the total average for the same hour taken from all observations of a given epoch.

It appears that on account of the extreme difficulties of the measurements, which were vividly described in Prof. Miller's presidential address before the Kansas Meeting of the American Physical Society, the results of the Michelson experiments are less trustworthy and less stringent than they have been supposed to be. The Trouton Noble experiment offers considerably less difficulty, and its negative result may be regarded as more convincing. Dr. R. Tomaschek, of the University of Heidelberg, has repeated this experiment at an altitude of 11,400 ft. at the Jungfraujoch, Switzerland (*Ann. d. Phys.*, vol. 78, p. 743, 1926). The observed effects did not exceed the errors of observation, and it was concluded that there is no relative velocity of the ether greater than 3 km./sec. at the given altitude.

This result gives rise to doubts concerning the significance of the interference shifts observed at Mt. Wilson. The doubts are augmented by the great irregularity of the measured shifts and by the predominance of the north-western direction in the diurnal variation of the effect, which is inconsistent with the assumption of an ether drift of constant 'absolute' direction.

My conclusion is, therefore, that the effect must not be attributed to any cosmic cause at all, but may be due to local disturbances.

The Molecular Spectrum of Carbon Dioxide.

THE value of the specific heat of carbon dioxide indicates a triangular molecule. Bjerrum (*Deutsch. Phys. Ges.*, **16**, 737, 1914) has made a study of this molecule and has decided that the atomic nuclei lie at the corners of an isosceles triangle the apex angle of which is either 145° or 40°·6. Dennison (*Phil. Mag.* (7), 1, 195, 1926) decides in favour of the former angle. Such a model, according to these authors, should be characterised by three fundamental vibrational frequencies. Each tries to associate the three well-known bands of absorption at 14·66μ, 4·25μ and 2·73μ with these predicted frequencies. The model does not anticipate a fourth weak band which I found at 2·02μ (*Phys. Rev.*, **26**, 469, 1925), especially since this is not harmonic with any of the other three.

Dennison associates the 4·25μ band with a motion of the carbon nucleus perpendicular to the bisector of the apex angle, and the other two bands with motions of the oxygen nuclei along the line joining them, the carbon nucleus moving along the bisecting line in such a way as to keep the same molecular configuration. In attempting to identify the observed relative intensities of these three bands with his predicted amounts, he meets with success in the case of the two longer wave-lengths but fails in the case of the third one. For whereas this band should be only 1/180th so intense as either of the other two, it actually is found to have 1/4th their intensity.

A new explanation for the presence of the 2·73μ band as well as of the weaker 2·02μ band has been sought on the basis of combinations of the frequencies of the strongest two bands. Table I. shows that the frequencies of the two weaker bands are approximately equal to $\nu_a' + 2\nu_a$ and $\nu_a' + 4\nu_a$ respectively, where ν_a' and ν_a are the frequencies of the 4·25μ and 14·66μ bands.

TABLE I.

ABSORPTION BANDS OF CARBON DIOXIDE.

		Designation	Calc.	Diff. Per cent.
14·66	68·9			
4·25	235·5			
2·73	366·3	$\nu_a' + 2\nu_a$	373·3	1·9
2·02	495·0	$\nu_a' + 4\nu_a$	511·1	3·2

Emission bands corresponding to each of the carbon dioxide absorption bands, including the newly observed weak one at 2·02μ, have been found in the spectrum of the Bunsen flame. Table II. shows the values of these bands, as well as the agreement of the frequencies of the weakest two with values calculated on the basis of combinations similar to those of Table I.

TABLE II.

EMISSION BANDS OF CARBON DIOXIDE.

λ in μ.	ν in mm.$^{-1}$.	Designation	Calc.	Diff. Per cent.
14·1	70·8	ν_e		
4·4	227·0	ν_e'		
2·76	362·0	$\nu_e' + 2\nu_e$	368·6	1·8
1·99	502·0	$\nu_e' + 4\nu_e$	510·2	1·6

It will be noticed that in every case the calculated combination frequenoies are somewhat larger than the observed values. This should be anticipated if we are to associate the terms $2\nu_a$, $4\nu_a$, etc., with approximate harmonic vibrations of some portion of the molecule; for the so-called harmonic vibrations arise from causes which also produce deviations from true overtone relationships, namely, the non-linearity of the force and the finite amplitudes of motion of the nuclei. Thus in the case of hydrogen chloride the first harmonic absorption frequency differs by 1·7 per cent. from a true multiple relationship (Brinsmade and Kemble, *Proc. Nat. Acad. Sci.*, **3**, 420, 1917), while extrapolation of the frequencies which I have observed to be characteristic of the C-H bond in all organic substances (*Phys. Rev.*, **27**, 298, 1926) indicates a corresponding deviation of 1·85 per cent.

Comparison of the above data shows an increase in frequency in the case of the longest wave-length band in passing from absorption to emission, while an opposite change characterises the 4·25μ band.

This in itself suggests separate origins of the two frequencies within the molecule. Furthermore, it suggests a strengthening of one type of bond and a weakening of the other type when the molecule is subjected to the greater thermal agitation in the flame. This is indicative of a slight change in the molecular configuration.

Further support of the combination theory proposed above is the gradual predomination of the lowest characteristic vibration frequency in the combination bands. This is shown in the approach toward equality in the $2{\cdot}73\mu$, $2{\cdot}76\mu$ bands, and the greater frequency value of the emission band in the case of the $2{\cdot}02\mu$, $1{\cdot}99\mu$ band.

Higher Order X-ray Reflections from Fatty Acids.

As is known from recent researches, especially in the Davy Faraday Laboratory, X-ray reflection from fatty acids shows the existence of a long spacing, which increases proportionally to the number of carbon atoms in the molecule. Using fatty acid crystals, we have succeeded in observing reflections up to a very high order. We were able to verify the work of Müller, Shearer and others; on the other hand, some new facts were brought to light.

Flaky crystals several millimetres square (the long spacing of which is normal to their surface), obtained by crystallising from acetone, were mounted on the calcite crystal of the X-ray spectrograph; lines due to the latter crystal served as reference lines. Iron-, copper-, and zinc-radiation was used.

As had been found by Müller and Shearer, the 1st, 3rd, 5th . . . orders of reflection from the long spacings are much stronger than the 2nd, 4th, . . . orders. Shearer has shown that this feature may easily be understood by assuming a simple model for the scattering power [1] of the fatty acid molecule. Our photographs show some new complications for the higher orders, as may be seen from the accompanying diagram (Fig. 1). In the upper portion the observed intensities in the case of palmitic acid (C_{16}) are given. These were estimated by eye, much help for a correct estimation being afforded by the fact that $K\alpha$ and $K\beta$ lines appeared at the same time on the plates; the intensity of the $K\beta_1$ is known to be about 25 per cent. that of the $K\alpha_1$ line.

As may be seen from Fig. 1, in the neighbourhood of the 9th order, even and odd orders are about equally intense, whereas at the 16th order the even orders are by far the strongest (the 16th order is about as intense as the 5th).

This intensity-distribution may be accounted for in its main features by a little more detailed model for the scattering power of the molecule [2] than that used by Shearer. Such a model is given in the right-hand part of the figure. As in Shearer's model, two molecules are placed end to end in opposite directions. At one end of the molecule a deficit of scattering matter (CH_3 group) is found; at the other end a surplus (COOH group). Calculations based on this model give for the intensity of the rth order:

$$I_r = \left[\frac{\sin\left(\frac{r\pi}{12}\right)}{r}\right]^2 \text{ when } r \text{ is odd,}$$

$$I_r = \left[\frac{\sin\left(\frac{r\pi}{12}\right) - \sin\left(\frac{r\pi}{24}\right)}{r}\right]^2 \text{ when } r \text{ is}$$

These calculated intensities are given in the lower portion of Fig. 1. Bearing in mind that the assumed model is far too simple to express the real state of things, and that, in addition, no correction was applied to the observed intensities, the agreement between calculated and observed values must be called very satisfactory.

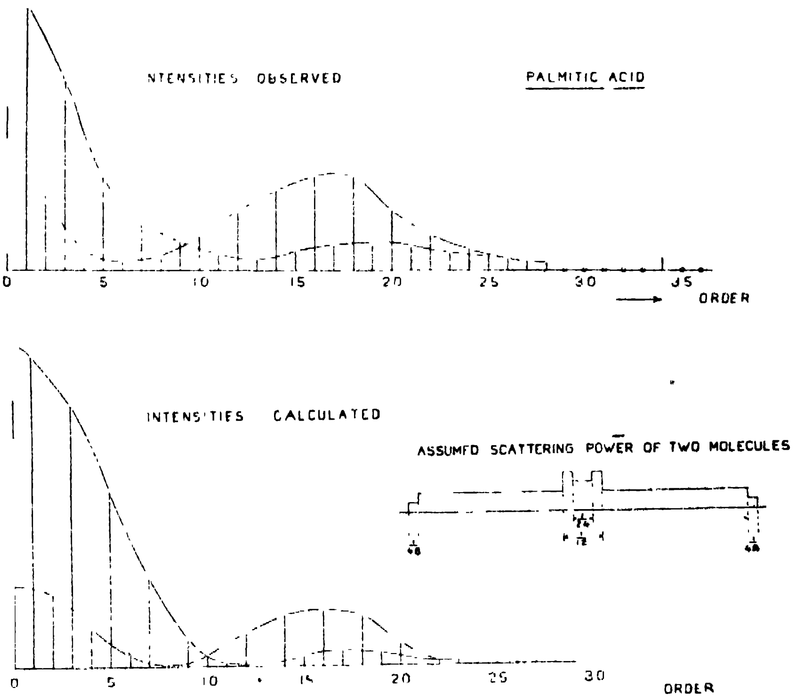

FIG. 1.

Similar results were obtained with lauric (C_{12}) and stearic (C_{18}) acids. In the first case a maximum of intensity for the even orders occurs at the 12-14th order; in the second case, at the 18-20th. In these cases the observed intensities may be accounted for by similar models for the molecules with the same dimensions of COOH and CH_3 group.

A very remarkable fact has been revealed in the case of palmitic and lauric acids The 34th order of palmitic acid (see Fig. 1) appeared distinctly in four hours on our photographs, whereas other orders higher than the 28th could not be detected even with exposures varying from six to eight hours (such orders sought for but not observed are indicated in the figure by small circles). In the same way the 26th order of lauric acid was clearly visible, no other orders higher than the 21st being detectable. In the case of stearic acid, our crystals were

[1] In this case the scattering power may be assumed proportional to the number of electrons belonging to the different atoms in the molecule.

[2] Strictly speaking, the distribution of scattering matter in planes normal to the long spacing governs the intensities of the different orders, but in this and similar cases this distribution is intimately related to the structure of the molecule; most probably the molecules are inclined at a definite angle to these planes.

unfortunately not good enough to go on to the corresponding (38th) order.

We are inclined to conclude that this singularity of the 34th order of palmitic and 26th of lauric acids depends upon the fact that the scattering matter is not uniformly distributed along the chain of the molecule, but contains a periodicity due to the successive CH_2 groups. The following facts seem to support this view. For twice the long spacing of palmitic acid we found 71·20 Å.U., and in the case of lauric acid, 54·45 Å.U. This means an increase per single CH_2 group of 1·045 Å.U. If we may assume this to be the mean distance of successive CH_2 groups, the double molecule of palmitic acid would be to a very high approximation 34 times this distance, and that of lauric acid 26 times.

The investigations are being continued with other chemical compounds

Our samples of fatty acids were furnished by the kindness of Dr. Treub, chemist at the Kon. Stearine-kaarsenfabrieken at Gouda.

Transmutation Experiments.

SINCE so large a proportion of the discussion relating to the reported transmutation of mercury into gold has been carried on in the columns of NATURE, it may be of interest to communicate briefly the results of experiments which have been in progress for some time in this laboratory, fuller details of which will be published shortly.

Various experimental arrangements were employed, but in no case has it been possible to establish the production of gold from the mercury. In the earlier experiments a condensed discharge, at a peak voltage of 15,000, was passed (*a*) between tungsten electrodes immersed in a fine emulsion of mercury droplets in white paraffin oil, (*b*) between aluminium rods in an emulsion of mercury in distilled water, and (*c*) between an iron pole and a mercury surface in an atmosphere of hydrogen. Secondary currents up to 75 ma. were passed for as long as twelve hours, but with uniformly negative results.

The most decisive experiment, however, was one which was designed to reproduce as nearly as possible the electrical conditions obtaining in Miethe's experiments with the rotating mercury interrupter, while reducing to a minimum the very grave danger of contaminating the mercury by contact with foreign substances. The mercury was sealed up in an atmosphere of hydrogen in a small quartz tube attached to a shaking machine, so that an arc was formed between pure mercury poles and drawn out to extinction six or eight times per second. A 30-ampere arc at 100 volts was run for 144 hours, followed by an 18-ampere arc at 240 volts for an equal period. During the last 24 hours of this run the tube was made to function as the interrupter for an induction coil, the secondary of which maintained a condensed spark discharge in air. Only 18 gm. of mercury was employed, and this remained perfectly bright and uncontaminated to the last. It was dissolved up at once in nitric acid, without being subjected to distillation, and a direct simultaneous determination proved that 10^{-8} gm. of gold could have been detected with certainty under the conditions of the experiment. No trace of gold was found.

The most conservative calculation based on the results of Miethe (*Zeitschrift f. anorg. Ch.*, **150**, 350, 1926) leads to an expected yield of 0·11 mgm. of gold, or at least 10^4 times the quantity which could not have escaped detection had it been present. Since the electrical conditions were identical in all essential respects with those in Miethe's experiments, it seems necessary to conclude, with Haber (*Naturwissenschaften*, May 7, 1926; NATURE, May 29, 1926), that Miethe's gold was derived from the materials of his electrodes and his vessels.

The mercury used in these experiments had been twice distilled, below 200° C., at the rate of about 100 gm. per hour, in mercury stills of quite ordinary design, and in no single instance could any trace of gold be recovered from the distilled mercury. The writer shares Miethe's opinion that the contrary results of other investigators have been due to mechanical carrying over of the amalgam, rather than to a true distillation of the gold.

An attempt to prepare indium from tin, by a similar method, also failed, though the spectroscopic method of detection was so delicate that great difficulty was experienced in obtaining indium-free tin for the experiments. A further attempt to produce scandium from titanium by electronic bombardment in an X-ray bulb proved equally unsuccessful.

Experiments are in progress upon the reported transmutation of lead into thallium and mercury. Obviously, no artificial production of such a common element as mercury can be regarded as established without the greatest rigour of proof that every possible source of contamination has been eliminated. The difficulty of completely excluding mercury has been well shown by its frequent appearance in the spectrum from the tin tubes, in which it was hoped to produce indium.

The New Element of Atomic Number 61: Illinium.

IN their interesting note on the discovery of illinium (NATURE, June 5, p. 792) upon which the authors, Messrs. Harris, Yntema, and Prof. Hopkins, may be congratulated, I find the statement that "there were no theoretical grounds for supposing that eka-neodymium [sic!] might exist until Moseley's rule showed that element number 61 was still to be identified." Having devoted almost all my scientific life—since 1877—to the theoretical and practical study of the elements of the rare earths, and especially to the question regarding their position in Mendeléeff's periodic system (the object was not very popular forty-eight years ago!), one of the results of which was the decomposition of the old didymium in 1882, I arrived at the conviction that the gap between the neodymium and samarium was abnormally large. In my paper read before the Bohemian Academy and the Russian Association of Scientists in St. Petersburg in 1902, I came to the conclusion—not reached by any chemist before—that the following seven elements, possessing now the atomic numbers 43, 61, 72, 75, 85, 87, and 89, remained to be discovered. As regards element No. 61, the difference between the atomic weights of Sm - Nd = 6·1, and it is greater than that between any other two neighbouring elements. It is remarkable that it is of the same order as that between the atomic weights of Mo - Ru = 5·7, between which stands ekamanganese, and of Os - W = 6·9, between which stands dwimanganese, recently discovered in our laboratory by Heyrovský and Dolejšek.

Personal knowledge of the chemistry of neodymium—the spectrum (absorption) I thought too complicated—and samarium brought me to the conclusion that also between those two elements an unknown element was missing, but all investigation by old methods was fruitless. Another reason may also be of interest. On arranging the true hydrides (in which the hydrogen is negative towards the positive metal) of the elements of the 8th series of the periodic system according to the order of their atomic weights, we find the following remarkable regularity of the composition of those peculiar compounds:

$$CsH_1, BaH_2, LaH_3, CH_4, PrH_3, NdH_2, (XH_1), SmH_0.$$

As samarium does not combine with hydrogen (Muthmann) there must exist between neodymium and samarium an unknown element which forms the hydride XH—*and this element is illinium.* My speculation has not proved futile.

Bohemian University,
Prague, June 12.

Identity of *Herpetomonas papatasii* and *Leishmania tropica*.

THREE successful experiments have been recorded by us in which cutaneous leishmaniasis was transmitted to man by inoculation of *Herpetomonas papatasii* from naturally infected sandflies (*Phlebotomus papatasii* ♀♀) (*Annals of Trop. Med. and Parasitol.*, vol. 20, No 2). Noguchi ("Action of Certain Biological Chemical and Physical Agents upon Cultures of Leishmania; Some Observations on Plant and Insect Herpetomonads." International Conference on Health Problems in Tropical America, 1924) and Kligler ("The Cultural and Serological Relationship of Leishmania." *Transact. Roy. Soc. Trop. Med. and Hyg.*, vol. 19, Nos 5 and 6, 1926) have introduced methods of preparing immune sera and distinguishing *Leishmania tropica*, *L. donovani*, and *L. braziliense* by agglutination. Agglutination and cross agglutination experiments with cultures from the three experimental lesions and three strains from naturally acquired lesions (two from Palestine and one from Baghdad) definitely proved the identity of the organisms from the experimental lesions with *Leishmania tropica*. *Herpetomonas papatasii* is, therefore, a synonym of *Leishmania tropica*, and the fact that *Phlebotomus papatasii* is a natural transmitter of cutaneous leishmaniasis is completely established, since in addition to the evidence of experimental transmission the Herpetomonas naturally occurring in the above insect is shown to be biologically identical with *Leishmania tropica*.

We hope to publish shortly complete details of our experiments elsewhere.

Pernicious Grafting.

THE Madeira agriculturist will be glad of any enlightenment on a devitalising influence frequently experienced in grafting a vigorous wild peach or nectarine seedling with a scion from a cultivated example. The wild seedling germinates from any chance seedstone thrown upon our terraces and develops rapidly into a sturdy tree, almost evergreen in character, crowded in the late autumn with a wealth of fascinating flower before the deciduous annual iage has left the branches bare, and yieldi early spring onwards an overwhelming crop of disappointing fruit.

If such a stock is cut across and grafted from a more worthy example in February, organic union is perfectly established and the new grafts speedily develop into sturdy ligneous growth which, by November, exhibits a promise of the vigorous output of leaf and flower customary in the wild seedling. But something now happens, and the tree, paralysed or devitalised, passes through the winter and spring months without a single leaf- or flower-bud breaking forth into activity.

Vitality is entirely suspended, and the tree is apparently poisoned by the introduction of an incompatible sap, although a modified life or mere existence may endure indefinitely. The removal of the intrusive grafts is unavailing, for the condition is all-pervading and not one of local obstruction.

Madeira is scarcely four days distant from the London markets, and it is of economic and commercial importance to remove any impediment to the almost perennial output of our sun-ripened produce.

MICHAEL GRABHAM.

Madeira, June 24.

Organo-Metallic Compounds.

AN X-ray investigation of the structure of the series of compounds carbon-, silicon-, germanium-, tin-, and lead-tetraphenyls, now almost completed, appears to indicate an interesting field of research in the organo-metallic compounds. It is proposed to extend the work to other series of these compounds so that after a time a systematic study may be made of the effects of varying (i.) the element, and (ii.) the groups. In order that this may be attempted, the writer appeals to chemists for the loan of small quantities of any related organo-metallic compounds which may be stable solids in air at ordinary temperatures.

To give an idea of the quantity of material sufficient for this work, it may be stated that the crystal of germanium tetraphenyl kindly lent by Prof. G. T. Morgan and found to give satisfactory results measured only 1·5 mm. by $[0{\cdot}065 \text{ mm.}]^2$, whilst from 0·15 gm. of powdered tin tetraphenyl kindly lent by Mr. A. E. Goddard, Mr. W. B. Saville, who is co-operating with me in this work, was able to grow a number of crystals suitable for use on both the photographic and the ionisation X-ray spectrometers.

WM. H. GEORGE.

Blood Reactions and Sex.

THE method elaborated by Manoilov for distinguishing the sexes has been used by us in the case of the fowl. Male can certainly be distinguished from female by this test. Seven birds which previously functioned as hens but now, having undergone complete sex-reversal, are fecund and potent cocks, all exhibit the female reaction indubitably. This being so, this test may be expected to provide valuable corroborative evidence concerning the genetic sex of certain kinds of sexually abnormal individuals.

The reaction in the case of blood from a fowl from which the gonadic tissue has been removed is, in our hands, not yet sufficiently definite.

University of Edinburgh.

X-Rays and Living Matter.[1]

By Prof. J. A. CROWTHER, University of Reading.

THE possible importance of X-rays in the medical world was recognised so clearly by their discoverer, Röntgen, that the first communication on the subject was made by him to a medical society, and was published to the world in a medical journal. Nor were medical men slow to appreciate the potency of the weapon which had thus been placed in their hands. The medical profession, be it spoken to its praise, has been unremitting in its search for new weapons in the fight against disease. Dr. Gilbert, himself no mean physician, and author of the first treatise on magnetism, records, with perhaps undue scorn, how, in the days when magnetism was the latest scientific marvel, patients were dosed with decoctions of lodestone as a possible panacea for all ills. It was not likely that so startling a discovery as X-rays would be overlooked, and we find medical men among the pioneers of X-ray work in nearly all countries. Further, the economically effective demand of medical radiology for more power, and still more power, has persuaded engineers and manufacturers to produce the modern high-power X-ray plant which has made possible the recent advances in the subject.

It was discovered early, but unhappily not early enough, that whatever healing power the radiation might possess, its destructive power on human tissue was indubitable and great. Few of the pioneers of radiography and radiotherapy escaped the painful and intractable X-ray burn, which arises from too prolonged an exposure to the radiation, and not a few have died as a result of the injuries thus received. Their labours have not been fruitless, and X-ray treatment is now a standard part of the work of any properly equipped hospital. At the same time one can detect to-day a certain undercurrent of dissatisfaction among radiologists. The rays have not yet fulfilled all their expectations. In particular, in some grave diseases where remarkable cures have been effected by X-ray treatment, a repetition of the same treatment in other apparently similar cases does not invariably produce the hoped-for result. There are undiscovered factors remaining to be elucidated. We need to ask how X-rays act on living matter, and in particular upon the living cell from which all living matter is built. The biologist, the physicist, and the chemist must be called in to assist, and the investigations must take in a wider sweep, before these problems can ultimately be solved. In science, as in other walks of life, it sometimes happens that the longest way round is the shortest way home.

It must not be supposed that so promising a field of research has been hitherto left uncultivated. There is, on the contrary, an overwhelming accumulation of observations and experiments. The results of different observers are, however, so conflicting that most of the evidence cancels out and leaves only a small residuum which can be said to be known with any certainty. This is scarcely surprising when we consider the conditions under which much of the work has had to be done. It is only within quite recent years that apparatus has been designed which makes it possible to repeat a given exposure with even approximate certainty, even with the same apparatus. It is not possible, even now, to give identical exposures if the apparatus is changed; if, for example, a high-tension transformer is substituted for an induction coil, or a Coolidge tube for a gas tube. Each type of apparatus for producing X-rays, one might almost say each individual set, has its own peculiarities, which are reflected in the quality and quantity of the radiation it produces. Our present state of knowledge does not allow us to assume that any of these variations have a negligible effect on the results.

Nor is there, at the present moment, any standardised or completely satisfactory method of recording these varied exposures. The properties of a given X-radiation are determined, physically, by its wave-length or frequency and its intensity. The radiation from an X-ray tube is, however, not monochromatic. It consists of a band of radiation stretching over a considerable range of wave-lengths. In optical terms, our X-ray tube gives us a continuous spectrum, which, moreover, may be crossed by intensely bright lines due to the characteristic radiation of the target from which the rays come. The band of maximum intensity moves towards the short wave-length end of the spectrum as the potential on the tube is increased, but the radiation is always mixed. In fact, for a given current, we shall get a larger absolute output of radiation of long wave-length from a tube working at high potential than from one at low potential. The distribution of energy in this complex spectrum depends on the wave-form of the high-tension apparatus used to supply the X-ray tube, and on the tube itself. If, as seems quite possible (there is ample experimental evidence both for and against the supposition), the biological effect is a function of the wave-length, it becomes a matter of considerable importance to determine not only the extreme wave-lengths but also the distribution of energy between the different wave-lengths in the radiation used. The discoveries of Prof. Laue, and their ingenious applications by Sir Wm. Bragg, have rendered this possible, but in very few researches so far conducted on the action of X-rays on living matter has any attention been paid to this important factor.

The measurement of the intensity of the radiation is a still more difficult problem, and one which cannot yet be said to have been solved by the physicist. The ideal method would be to measure the energy in the beam by absorbing it completely in some heavy metal, such as lead, and measuring the heat produced. Unfortunately, the actual energy even in a powerful beam of rays is so minute that, although it has been detected, it would strain the resources of a well-equipped physical laboratory to measure it with any accuracy. It is necessary to fall back upon some secondary property of the rays. The only secondary property which is capable of being measured with the necessary accuracy is that of producing ionisation in any gas through which it passes. Gas through which X-rays are passing becomes feebly conducting to electricity

[1] Substance of a course of two lectures delivered by the author at the Royal Institution on January 19 and 26.

and the current which can be passed across the gas is a measure of the ionisation, and thus, indirectly, of the intensity of the radiation. Prof. Friedrich has proposed that the amount of X-radiation which will allow a charge of one electrostatic unit to pass across one cubic centimetre of air shall be taken as the unit quantity of X-radiation. This proposal has met with some opposition, but personally I do not see the possibility of finding a better unit, at any rate in the immediate future. At least it may be affirmed that until experimenters can agree upon some method of measuring their quantities, progress is not likely to be rapid.

If any apology should appear to be needed for devoting so large a portion of our space to the question of measurement, it is certainly provided, not merely by the large mass of painstaking observations which have been rendered almost nugatory for want of it, but also by the records of recent work in the subject. Everything, in fact, seems to indicate that the biological effect of the rays may vary in a perfectly astounding manner with quite trifling variations in the magnitude of the exposure and the wave-length of the radiation. Only within the last few months a paper has come through from Australia, in which the author, Dr. Moppett, claims to have demonstrated a selective effect of the radiation of surprising sharpness. Dr. Moppett spread out his beam of X-rays into a spectrum, by means of a Bragg spectrometer, and exposed one of the important membranes of an ordinary chicken embryo in turn in various parts of the spectrum. He found that at certain definite positions in the spectrum, that is to say for certain definite wave-lengths of the radiation, the cells in the membrane were rapidly killed by the action of the rays, while much longer exposures to neighbouring wave-lengths produced no effect. The effective radiations had wave-lengths of 0·11, 0·53, and 0·79 Angström units. Wave-lengths differing by only a few per cent. from these values were quite inoperative.

The paper, it must be confessed, is sadly lacking in the details which a physicist requires to assess its accuracy, and in many particulars it is by no means clear. One would certainly not have expected to obtain a selective effect with radiation of so short a wave-length as 0·11 A.U., and if this result is verified we may have to revise some of our physical ideas as to the absorption of X-rays by matter. It is desirable that Dr. Moppett's work should be repeated. If, however, for the moment we accept these results, it is not difficult to point the moral. The wave-length 0·11 A.U. is somewhere near the limit of the spectrum for a hard X-ray tube. It requires for its excitation a voltage across the tube of about 120,000 volts. Suppose the experimenter to be working his tube somewhere about this voltage. A slight rise in the voltage will produce a copious supply of the deadly radiation. On the other hand, if the voltage falls by but a small amount this radiation may be absent altogether. A trifling change in the supply voltage, to which few of us would, in practice, pay any attention, may thus completely alter the nature of the results obtained.

Experiments indicate that the margin in the case of the dosage given is equally narrow. Although the effect of a prolonged exposure to X-rays is invariably lethal, small doses often produce a healthy stimulation. This has been proved, by Prof. Russ among others, in the case of rats. It is also very evident in the case of Protozoa. I have found that an old culture of *Colpidium Colpoda*, for example, may be stimulated to new growth and active division by a suitable dose of radiation. The margin between stimulation and death is a very narrow one. In fact it is possible, by a careful adjustment of the dose, to have as the result of a single exposure individual colpidia, showing every sign of stimulation, swimming about vigorously among the corpses of those which have been killed by the same dose. A slight increase in the dose, say an extra ten per cent., will kill off the whole culture. A decrease of ten per cent. produces only stimulation. It is clear, in this instance at any rate, how narrow is the margin which separates these diametrically opposite effects. In radio-biology—if we may be permitted to coin the word—as in other sciences, exact measurement is the key which unlocks the door of knowledge.

It is no part of the purpose of this article (the attempt would be impossible in any case) to give a résumé of the vast amount of observations made on the action of X-rays on living matter. It is doubtful whether most of them can throw much light on the fundamental problem which underlies them all. In irradiating an animal, or even a tumour growing on an animal, we are dealing with a part of a highly organised and closely interrelated structure, and any effects which are observed may be merely secondary and only indirectly due to the irradiation. So true is this that it applies even to the parasites on the body. Bacteria, for example, are notoriously resistant to the action of the rays when exposed in a pure culture. On the other hand, the same bacteria infecting a wound will often be killed by quite small exposures to the radiation, and such exposures are now frequently used as a means of clearing and healing a wound. The problem, difficult enough in any case, only becomes manageable if reduced to its simplest form, and the simplest form in biology is the individual cell.

We are fortunate in possessing at least a preliminary study of the effect of X-rays on the individual cell. Methods have now been perfected by which it is possible to remove a number of cells from the tissues of a live animal and to cultivate them for long periods in glass vessels, where they continue to thrive and multiply, quite independently of the fate of the animal of which they were once a part. Dr. Strangeways has studied the action of X-rays on these isolated cells, and a preliminary account of his work was communicated a year or so ago to the Royal Society. One of the striking facts which emerges from his work is that it is extremely difficult to destroy a resting cell by the action of the rays. Doses far heavier than could be safely applied to the human skin leave them apparently unaffected. Further observation, however, showed that this absence of effect was only apparent. The cells had been very vitally affected, but the effects of the rays only became visible when the cells began to divide.

The first effect of the rays, produced by quite short exposures, was to lessen very materially the number of cells passing through the process of cell division, or mitosis. Dr. Strangeways records that an exposure of only 5 of Prof. Friedrich's units produces an

appreciable diminution in the number of cells passing into mitosis. With a dose of 10 units the number was still less. After 15 units only a few cells in mitosis were visible, but the phenomenon was seen occasionally until the exposure reached as much as 85 units. Thus while a small dose of X-rays is sufficient to prevent the majority of the cells from dividing, a much larger dose is required before the whole of the cells are affected.

Dr. Strangeways has not yet provided us with a numerical estimate of this effect, but we hope that he and his collaborators may be able to do so before long. In the meantime, if we attempt to express his descriptions graphically, the curve which we shall have to draw relating the number of cells in mitosis with the exposure to the rays will be one which, plunging rapidly downwards at first, approaches zero asymptotically for prolonged exposures; it will, in fact, resemble closely an exponential curve. Now a curve of this type suggests strongly that the effect we are considering is a probability effect—in other words, that whether a cell will or will not go into mitosis after a given dose of X-rays is a matter of chance, the probability of its not doing so becoming greater as the dose is increased. This variability may, of course, be in the cell. Some may be more susceptible to the action of the rays than others. It is always legitimate, though not very helpful, to invoke the biological factor. I have ventured to suggest the possibility that it has nothing to do with the cell, but lies in the nature of the agent which we are using against the cell, that is, in the X-rays themselves.

An analogy, which is in fact a very close one, may help to make the matter clear. Suppose that we were firing at a swarm of midges with a machine gun. The number we should hit per second would be proportional to the number present in the swarm. At first we should claim a large number of victims, but, as the swarm gradually melted under our fire, the chance of hitting a midge would become smaller and smaller. To hit the last two or three would entail the expenditure of much ammunition and considerable patience. The survivors, however, would not owe their prolonged existence to any biological factor, or to any immunity either inherent or acquired, but simply and solely to their good luck. The number of survivors would, in fact, decrease exponentially as the number of bullets fired into the swarm increased.

Now, as Prof. C. T. R. Wilson's photographs show us very graphically, a beam of X-rays is very much like a swarm of bullets—only a negligible proportion of the atoms in the path of a beam of X-rays are affected in the least by the passage of the beam. It is quite easy to show that if the rays are conveying a dose of one unit per minute, as was the case in Dr. Strangeways' experiments, an individual atom would be effectively hit by the radiation on an average only once in a million years. The probability of a hit increases with the size of the particle, and a tissue cell would receive on an average about 14 hits per second, but as a hit is a matter of pure chance some would clearly receive more and others less than the average. This variation becomes more important as the size of the particles becomes smaller, and some of the important structures in the cell are much smaller than the cell itself.

It is not difficult to calculate what size the structure must have to fit in with the curve which we have constructed from Dr. Strangeways' description, on the assumption that a single hit registered by the rays on this particle suffices to put the cell out of action. Its diameter, assuming it to be spherical, would have to be about 1/2500 m.m. This is of the order of magnitude of the centrosome, a body which is considered by many biologists to play an important part in the process of cell division. With a target of this size, half the cells would be put out of action with an exposure of 12 units, 25 per cent. would survive a dose of 24 units, while 6 per cent. would still be capable of mitosis even if the dose were increased to 48 units. It will be seen how closely these numbers fit the phenomena we have described. It seems possible, to say the least, that the quantum theory must be taken into account in biology as well as in physics, and that a single cell may have a much more direct and painful appreciation of the existence of quanta than is possible to our grosser senses.

The scanty data which we possess on the action of X-rays on living cells indicate that the simple exponential relation which we have suggested is rather exceptional. The curve relating the number of survivors to the dose of X-radiation is generally sigmoid in shape. Practically no effect is produced until the dose exceeds a certain value. After this point is reached the number of cells affected increases rapidly, but there are always a few which survive much larger doses than the average. Curves of this kind are given by Dr. F. C. Wood, as expressing the result of his recent experiments on the effect of X-rays on cancer cells *in vitro*. Theoretically, we get a relation of this kind if we assume that a definite succession of hits is required to produce the result we are aiming at—say, for example, the destruction of the cell. I have given a calculation of the form of the curve on this assumption in a recent paper before the Cambridge Philosophical Society. A very considerable amount of rather tedious work will be necessary before sufficiently experimental results can be obtained to afford a real test of the theory, but the results so far accumulated are distinctly promising.

It need not be emphasised that these attempts to drag the biological action of X-rays into the domain of physics are extremely tentative. It is possible, even probable, that in the ultimate issue we shall find in the living cell something which transcends all physics and chemistry, but this is no legitimate excuse for failing to push our sciences to their extreme limits. Whatever the ultimate result may be, we are sure to find much of interest by the way. The primary effect of the absorption of X-rays by an atom, in fact the only effect of which physicists are aware, is the expulsion of a high-speed electron from the atom. That, it would appear, must be the starting point of any purely physico-chemical theory of the action of X-rays on living matter. What subtle series of changes is thus initiated in the complex chemical compounds which make up the cell is a problem, like that of the song the syrens sang, the answer to which no man knows, but which may not be beyond the wit of man to conceive. Nature, as usual, leaves us guessing. That is precisely why we find her so fascinating.

The Rhynie Crustacean.

By Dr. W. T. CALMAN, F.R.S.

MR. D. J. SCOURFIELD'S memoir "On a new Type of Crustacean from the Old Red Sandstone (Rhynie Chert Bed, Aberdeenshire), *Lepidocaris rhyniensis*, gen. et sp. nov." (*Phil. Trans.* B, 415, 1926), which has already been noticed in NATURE (April 3, 1926, p. 498), is so important a contribution to arthropod morphology that no excuse is needed for directing further attention to some of the problems suggested by it.

In the first place, it should be emphasised that no other fossil crustacean is known with anything approaching the completeness with which Lepidocaris has been described by Mr. Scourfield. The only fossil arthropod, and in fact the only fossil invertebrate, which comes near it in this respect is the well-known *Eurypterus fischeri* as described by Holm. In the second place, in spite of its antiquity, Lepidocaris is far from being a primitive crustacean. In some respects (notably in retaining the biramous swimming antennæ of the nauplius) it is indeed more primitive than the existing Anostraca, but it shares with them many characters that are by no means primitive, such as the simplified mouth-parts, which are much more specialised than those of many Copepods. The development of male claspers, of Anostracan type, from the maxillulæ instead of the antennæ, is a surprising feature, the significance of which remains obscure. It may indicate that Lepidocaris is off the main line of Anostracan descent. It is doubtful also whether the absence of eye-stalks can be regarded as a primitive character.

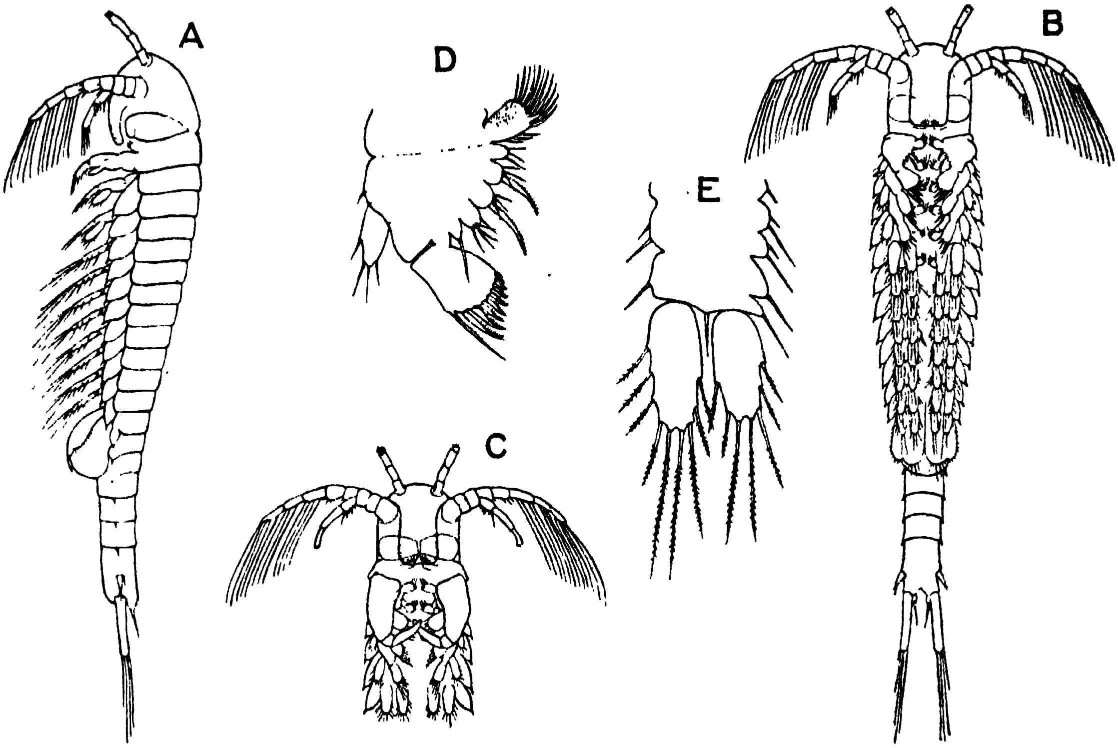

FIG. 1.—Restorations of *Lepidocaris rhyniensis*, Scourfield. A. Female, from the side. B. Female, from below. C. Male, anterior part of body from below. D. One of the first pair of trunk limbs. E. One of the trunk limbs of the posterior (seventh to eleventh) pairs. Approximate magnification, A, B, and C×27, D×9, E×10. (After Scourfield.)

One of the most difficult problems of crustacean morphology has been the correlation of the biramous type of limb found in so many Crustacea with the 'phyllopod' type seen in the Branchiopoda. Since Ray Lankester, in his classical memoir on Apus, showed that the Branchiopoda (or Phyllopoda) are the most archaic of living Crustacea, it has been generally accepted that the biramous has been derived from the phyllopod type. Lankester argued that the two branches of the biramous limb, the endopod and exopod, were derived from the two distal 'endites' or lobes of the inner edge of the phyllopodium. Huxley had earlier identified the exopod with the 'flabellum' of the Phyllopod and the endopod with the distal part of the stem or 'corm,' and this interpretation has been adopted by others, notably by Dr. Borradaile in a recent paper.[1] Lepidocaris would seem to provide the answer to this question, for while the first three pairs of its trunk appendages are phyllopodia, comparable without much difficulty with those of recent Branchiopoda, the following limbs are biramous; and it is perfectly clear that the exopod of the posterior limbs is equivalent to the flabellum of those in front, the endopod being the distal endite.

Dr. Borradaile inclines to the opinion that, in the

[1] "Notes upon Crustacean Limbs," *Ann. and Mag. Nat. Hist.* (9), 17, p. 193, 1926.

evolution of the Crustacea, the biramous form of limb has been arrived at more than once by different modifications of the phyllopod type. In view, however, of the simple biramous form of the limbs in the nauplius larva and in the Trilobites (the close relationship of which to the Crustacea cannot now be doubted), and of the persistency with which the same type emerges in the most diverse groups of Crustacea, it seems more reasonable to assume that it represents the deep-seated plan of symmetry on which all crustacean limbs are built. It is indeed possible that the phyllopod type preceded the biramous and that Lepidocaris preserves the transition from one to the other. This would seem to be the view taken by Mr. Scourfield, who, although he gives us little in the way of speculation, does imply that the biramous hinder limbs of Lepidocaris are derived from the phyllopodous type of those in front. It is, however, a very general rule among Arthropoda that specialisation begins anteriorly and works backwards; we should expect the posterior limbs to be the more primitive; and Lepidocaris gives the impression of having had primitively biramous limbs of which the more anterior pairs have been specialised in adaptation, no doubt, for some special method of collecting food.

A minor problem is presented by the lateral row of large scales (to which the generic name alludes) covering the bases of the trunk limbs. These suggest the small scales at the base of the outer edge of the limbs in Anostraca which are generally interpreted as the proximal exites of the limbs. In Lepidocaris, however, at the posterior end of the series, the scales are seen to be merely the pinched-off pleura of the somites. It is a matter for further inquiry whether the proximal exites of the Anostraca may not also be of pleural origin.

Perhaps the most unexpected feature of Lepidocaris, however, is the structure of the last segment of the body. In many Crustacea, in the larva if not in the adult, the termination of the body is forked. Very often this fork is nothing more than a notch in the hinder edge of the telson, but sometimes the two prongs of the fork are movable rods jointed to the segment, and in a few cases (Notostraca, Cirripedia) they are long, many-jointed filaments. In Lepidocaris we see clearly, for the first time, that these movable appendages are not, as has been generally supposed, homologous with the two branches of the notched telson. In the earliest larva found the telson is notched, and this notch persists in the adult to form what Mr. Scourfield calls the "primary furca." In the later larvæ, however, a pair of rod-like appendages grow out at the sides of the primary furca and become separated by articulation from the body of the telson, forming a "secondary furca" which is evidently the homologue of the articulated furca of Anostraca, Copepoda and Phyllocarida. In still later larvæ a second smaller pair of appendages appear at the sides of the telson in front of the secondary furca. Just above the articulation of each of these two pairs of appendages is set a small spine. The somites immediately in front of the telson bear no appendages, but each has, on either side, a similar spine, and as these spines are traced forwards they are plainly seen to be in series with the spines which tip the lateral scales already mentioned above the insertion of the limbs.

It seems impossible to avoid the conclusion that the appendages of the telson in Lepidocaris and the furcal rami of the groups mentioned above are serially homologous with the true limbs of the anterior part of the body. Now it is the general rule in the development of Arthropoda that the somites and their appendages appear and become differentiated in regular order from before backwards, new somites being added from a 'formative zone' in front of the telsonic region. In Lepidocaris alone do we find evidence of true appendages on the telson itself, *behind* the formative zone; and, emphasising the singularity of their position, the order of their development is the reverse of that of the pretelsonic appendages, the hinder pair appearing first.

It must be borne in mind that, at the time when Lepidocaris lived, the Crustacea had already behind them a long evolutionary history. It is now known from Walcott's remarkable discoveries that, so early as the Middle Cambrian period, a varied crustacean fauna existed and that several of the forms had at least a superficial resemblance to Anostraca. Unless some chance discovery, as fortunate as that at Rhynie, and an investigator with Mr. Scourfield's indefatigable patience and skill, combine to reveal a great deal more than we know at present about the structure of these early forms, speculations on phylogeny must go very cautiously.

Obituary.

Dr. Edward J. Bles.

By the recent death of Edward J. Bles, zoological science has lost a devoted worker whose qualities of mind and character were of the highest. It is the faith of many of his friends that, but for factors of temperament, and health, he would have become a leader of thought in the subject of his choice. His publications, though of high merit, were relatively few; but his intimates know that they were far from representing all that he accomplished, and are aware of the temperamental restraints but for which he could and would have published much more. He was one of those investigators—deserving sympathy from colleagues with easier standards—who would fain allow publication to wait for perfection, and yet realise even better than others that perfection never arrives. In spite of such inhibitions, or perhaps because of them, his published output is of high value and stamped with the quality of absolute reliability.

For elementary teaching, or, at any rate, for the shackles of departmental teaching and organisation, Bles had some distaste. On the other hand, he was the ideal colleague and one of the most educative influences for the young research worker. He would give his time and ingenuity for days to devise methods for another's work; he was a most sincere and painstaking critic and there never was any one with whom it was more delightful to share the joys of discovery or the fruits of victory. Yet he greatly prized independence, and the freedom to work out his own ideas on his own

lines. Being possessed of sufficient private means, Bles was therefore finally led to avoid all official posts, and for nearly twenty years he worked, first at Iffley, Oxford, and later, until the end, at Cambridge, in private laboratories equipped by himself. This involved, of course, some degree of isolation, and the additional factor of weak health finally led him to become scientifically somewhat of a recluse. In visits from scientific friends, however, he always took the greatest pleasure, and, to the end of his life, those who had the privilege of paying such visits profited always from contact with a truly philosophic mind and a stimulating personality. His wide learning was at the service of all.

Born in 1864, he was the son of A. J. S. Bles of Manchester. When fourteen years old he was sent to a school in Hanover where the teaching of science seems to have been exceptionally good. Family interests led him at the age of eighteen years to start in his father's business at Manchester; but his own interests directed him from the first into scientific company. He joined the Manchester Microscopical Society and became its secretary. Thus arrived the turning-point of his life. He came under the influence of Milnes Marshall, who saw his bent and genius, and for whom Bles then acquired, and ever afterwards retained, great love and admiration. He joined the Owens College, attended Milnes Marshall's classes, and in 1890 became, with his teacher, joint author of papers dealing with the development of amphibia, a subject which for some time remained one of his chief scientific interests. About this time he went to occupy a table at Naples and returned to carry out the duties of junior demonstrator of zoology at the Owens College. From 1892 until 1894 he was Director of the Marine Biological Association's Station at Plymouth. He went up to Cambridge in 1895 and took a research degree in 1898. When Prof. J. Graham Kerr was appointed to the chair of natural history at Glasgow, Bles accompanied him as his assistant and remained at the University until 1907, when he went to live at Iffley, Oxford.

In 1911 Bles removed to Cambridge. Before his last migration his scientific reputation had been made by the publication of important papers; especially by one which appeared in the *Transactions of the Royal Society of Edinburgh* in 1905 on the life-history of *Xenopus Lævis*, and another dealing with the development of certain Anura published in the volume issued by the Cambridge University Press as a memorial to John Samuel Budgett. Of these two papers describing work of fundamental importance, Prof. W. E. Agar writes: "They are very characteristic of Bles' work and scientific attitude. He would take an immense amount of trouble over the smallest detail, lingering over it with a loving care. . . . The plates in these two papers could scarcely be surpassed, either for accuracy of detail or beauty of execution—the result of laborious co-operation between the author and the artist, Mr. A. K. Maxwell. It is worthy of note that these plates contain the first scientific illustrations produced by this artist whose work is now so well known to biologists." The interest of the artist in such work must have been stimulated by his early collaboration with an investigator like Bles, whose own love of accuracy and beauty of execution were so great.

After his Cambridge laboratory was equipped, Bles started to breed various species of rare amphibia, a difficult enterprise in which he had the assistance of his devoted wife. This work was carried out with elaborate care and led to most interesting scientific observations, especially with regard to certain little-studied aspects of metabolism, to the significance of which Bles was keenly alive. The most important work of his Cambridge period had been begun at Oxford. It consisted of an elaborate and highly original study of Arcella by microchemical methods, during which Bles developed a very beautiful technique and obtained results of great importance. Unhappily, the inhibitions to which reference has been made became exaggerated in his latest years, largely because of continued ill-health, and the results of this prolonged research, though known to many, have not yet appeared in print. A paper was practically finished, however, and very fine drawings are available for its illustration. Its publication will be secured in the immediate future under arrangements made in the author's will.

Bles was not merely a scholarly biologist in a very wide sense, he was also a man of fine general culture; music, literature, and the arts all made a vivid appeal to him. He had, moreover, a true sense of values and a very beautiful appreciation of the relative importance of things. His knowledge was of the widest, but so philosophic was the cast of his mind that synthetic thought was essential to him. He endeavoured always to see things as a whole.

F. G. HOPKINS.

PROF. V. A. STEKLOV.

PROF. VLADIMIR ANDREJEVICH STEKLOV, member and vice-president of the Russian Academy of Sciences, an eminent and well-known mathematician, died at Ialta (Crimea) on May 30.

Steklov was born in 1863 in the province of Nishni-Novgorod as the son of a country priest. He attended a classical school at Nishni-Novgorod and afterwards entered the University of Moscow to study medicine, but he soon left Moscow and went to Kharkov to study mathematics under Liapunov and became his most gifted pupil and lifelong friend. He graduated at Kharkov, took the usual degrees of magister and doctor of mathematics, and was appointed professor at this University. His first work, "On the Motion of a Rigid Body in a Fluid," was published in Russian in the *Memoirs of the Mathematical Society of Kharkov.* In this paper he found several new 'integrable' cases of this problem. His thesis for his doctorate was "On the Principal Problems of Mathematical Physics." Such problems formed the basis of his subsequent numerous investigations, extending over a period of nearly thirty years. In these investigations he established his "théorème de fermeture," relating to the development of arbitrary functions in infinite series of "fundamental functions" depending on the roots of transcendental equations. Such expansions occur frequently in mathematical physics, the Fourier series being the simplest special case. Steklov introduced the necessary rigorousness into the problems of mathematical physics, in proving the existence of the solutions and the conditions of convergence for the series used. He summarised his researches in a treatise "On

the Differential Equations of Mathematical Physics" recently published by the Russian Academy of Sciences in two volumes. The complete list of his scientific papers contains about 120 items. These papers are published mostly in French, in the *Memoirs of the Russian Academy of Sciences*, the *Annales de l'École Normale Supérieure*, the *Annales de l'Académie de Toulouse*, and others.

As a lecturer Steklov was widely known while he was professor in the higher branches of theoretical mechanics and mathematics, first at Kharkov and then at St. Petersburg (now Leningrad).

Steklov was elected a member of the Russian Academy of Sciences in 1910, and in 1919 became vice-president of the Academy. The task of the vice-president was at that time a most difficult one. The vice-president is responsible for all the administrative work of the Academy and of its numerous institutions; he has to control the yearly expenditure and to superintend the proper use of the funds. Steklov proved to be just as able an administrator as a man of science: with open mind, sound judgment and firm hand, he steered the Academy safely through the hardships of the years 1919–22.

A. KRILOFF.

WE regret to announce the following deaths:

Miss Gertrude Bell, oriental secretary to the High Commissioner of the Iraq, Baghdad, since 1920, and distinguished for her travels in and knowledge of the peoples of Arabia, on July 11.

Mr. A. G. Charleton, past president of the Institution of Mining and Metallurgy, and author of numerous works on ore-mining and treatment, on July 7, aged sixty-eight years.

Mr. W. Temple Franks, C.B., lately H.M. Comptroller-General of Patents, Designs, and Trade Marks on July 4, aged sixty-three years.

Mr. F. Harrison Glew, M.B.E., a pioneer in the utilisation of radium and its salts for the preparation of luminous paint and other purposes, on July 10 aged sixty-eight years.

Sir Peter Scott Lang, emeritus professor of mathematics in the United College at the University of St Andrews, on July 5, aged seventy-five years.

Dr. George R. Lyman, dean of the West Virginia College of Agriculture at Morgantown and previously pathologist in the Bureau of Plant Industry a Washington, D.C., on June 7, aged fifty-five years.

Rev. T. R. R. Stebbing, F.R.S., the distinguished naturalist and worker on Crustacea, on July 8, aged ninety-one years.

News and Views.

ON July 7, in the presence of a large and representative gathering in a spacious marquee, Mr. Neville Chamberlain laid the foundation stone of the new London School of Hygiene and Tropical Medicine, the result of a gift of 2,000,000 dollars from the trustees of the Rockefeller Foundation. The chairman of the Board of Management, Sir Alfred Mond, in introducing Mr. Neville Chamberlain, reviewed the steps which had led to the foundation of the School. He pointed out that the former Chancellor of the Exchequer, Sir Robert Horne, had recognised the great importance of such an institution and had agreed that the British Government should make itself responsible for its maintenance. As a result of representations made by Mr. Neville Chamberlain to the present Chancellor of the Exchequer the building was being expedited, a grant of 5000*l* per annum being made by the University Grants Committee and one of 4000*l*. per annum from the Rockefeller trustees for immediate developments. He was able to announce that though Sir Cooper Perry is retiring from the post of Principal Officer of the University of London, his services are being retained on the Board of Management of the School, of which he has consented to be vice-chairman. Mr. Ormsby-Gore, Under-Secretary for the Colonies, in a most lucid and convincing manner, spoke of his recent experiences on a tour of the colonies and his conviction that hygiene and sanitation are the most vital of all the problems connected with the future development of the vast territories under the charge of Great Britain. The importance of a school like that being founded in London could not be overestimated.

MR. NEVILLE CHAMBERLAIN said that the building, the foundation stone of which he was to lay, was a result of co-operation between the two great English-speaking nations. It had been noted that the teaching of public health in London is carried on in a number of separate institutions, and it was realised that its concentration in one school would undoubtedly conduce to greater efficiency in teaching and research work. It was further realised that public health is not only necessary in the British Isles, but is of even greater importance in the tropical possessions of Great Britain. It was this fact which led to the incorporation of the London School of Tropical Medicine, founded in 1899 by Mr. Joseph Chamberlain. The new School would deal with hygiene in its widest applications, and before it lies a future in which it would not only be of national but also of imperial and even world-wide importance. It is probably destined to be famous as the greatest centre in the world for research and instruction on one of the most beneficent of all the activities of the human race. Reviewing the departments of the new School Mr Chamberlain said these would comprise: (1) Physiology; (2) chemistry and bio-chemistry; (3) bacteriology and immunology; (4) epidemiology and vital statistics; (5) medical biology; (6) sanitary science and public health in general. The School would be fitted with the latest types of apparatus and equipment, and would develop a great teaching museum in graphic form, intended not only for the student of hygiene but also for those of the general public who would care to visit it. With this programme before it there is every prospect that post-graduate students would gather from all parts of the world, and there can be little question that men and women will receive the best possible instruction in the methods of disease prevention. After the foundation stone had been laid Dr. Andrew Balfour, Director of the School, presented Mr. Neville Chamberlain and Mr. Ormsby-Gore with seals as mementoes of the

important occasion, the success of which they had so ably ensured.

AT 29 Great Pulteney Street, Bath, a corporation committee, under the chairmanship of Mr. T. Sturge Cotterell, has erected the forty-second mural tablet in commemoration of distinguished people definitely connected with the city. This last one states that "In this house William Smith, the Father of English Geology, dictated 'The Order of the Strata,' December 11th, 1799." The house was that of the Rev. Joseph Townsend, and it was the Rev. Benjamin Richardson who held the pen. This, the first written statement of Smith's ideas, was distributed in many copies to geologists at home and abroad. The tablet was unveiled on July 10 by the president of the Geological Society of London, Dr. F. A. Bather, in the presence of the mayor and a company that included many leading geologists. The chief guests were entertained to lunch at the Guildhall by the mayor (Mr. Cedric Chivers) and mayoress (Madame Sarah Grand), after which a meeting at the Royal Literary and Scientific Institution was addressed by Dr. Bather.

DR. BATHER showed in his address how the conclusions of William Smith flowed naturally from his surveying work in the neighbourhood of Bath, and how the society of the city afforded a fertile field for their reception. Smith's leading ideas, a revelation to his contemporaries, formed the starting-point and the necessary foundation of all tectonic and all historical geology; they have been the only sure guide in the great industries of coal-mining and oil-getting; and they alone have afforded the proofs without which evolution would have remained an ineffective dream. Prof. W. B. Scott, of Princeton, emphasised some of these thoughts by reminding the company that Hutton himself had not conceived the possibility of an historical geology, and that among those who failed to understand the principles of William Smith even Herbert Spencer could be reckoned. Among other speakers were Profs. S. H. Reynolds and H. L. Hawkins, and the chairman, Mr. P. E. Martineau, who is doing so much to revive the geological museum of the Institution.

MATHEMATICIANS usually look to the British Association only to satisfy their curiosity as to progress in other subjects than their own, but for this year's meeting at Oxford an attempt is being made to provide a broad platform for expression among themselves. On three mornings Section A will divide, mathematics separating from astronomy and physics, and several speakers have undertaken to describe in terms intelligible to mathematicians generally, not merely to experts in one branch or another, recent lines of advance and outstanding problems that are being attacked in mathematics itself. Subjects are found in mathematical logic and in rational dynamics as well as in the central regions of analysis, and every problem is to be expounded by some one who is at work upon it. It rests with the mathematicians of Great Britain, amateur as well as professional, from the schools as well as from the universities, to prove by their attendance that an effort to give in simple language some idea of the present vitality of mathematics appeals to a genuine interest. Only a fraction of the possible subjects can be touched at one meeting, and if this year's experiment is successful, the British Association will have discovered a function which can be continued beyond the circle surrounding its present origin and may even be found to be regular almost everywhere.

THE interesting lecture given by Mr. C. F. Elwell on May 5 to the Royal Society of Arts on the past, present, and future of radio is published in the June number of the Society's journal. He divides the subject into radio telegraphy, telephony, and miscellaneous applications. He points out that it is possible to talk to ships at sea by an ordinary subscriber's telephone. Such relaying of wire line telephony has even been done after the speech has been transmitted 5500 miles. The rapid progress of broadcasting is due to the demand for it. There are already two million receiving sets in use in Great Britain, and five million in the United States. There is a field for the transmission of speech by radio over electric light wires and transmission lines. Considerable progress has already been made in this direction in Italy, Germany, and the United States. It will do much to relieve the overcrowded ether. The three-electrode valve has already cheapened the cost and considerably extended the field of telephony. A few years ago, conductors weighing 150 lb. per mile were necessary for long-distance transmission. Better speech is now possible over greater distances with conductors of only one-fifth the weight. Considering that millions of miles of telephone circuits are in existence and that extensive developments are in progress, the value of the copper that is being saved is very large. A picture of a cheque has been sent across the Atlantic by radio and has been honoured within an hour of its receipt. It is possible that picture films may be sent by radio. In the art of television notable progress is being made by J. L. Baird, and developments may be expected. Many problems in connexion with the prevention of collisions at sea and between aeroplanes in the air still remain to be solved. A solution of one of these problems would probably also be applicable to the other. Even in competition with submarine telegraphy, radio is making progress. Radio telegraphy carries 30 per cent. of the message traffic across the Atlantic.

ACCORDING to a telegram of July 6 from The Hague (printed in the *Times* for July 7), another serious earthquake since June 28 has occurred on the west coast of Sumatra, but the date is not given. The epicentre is said to lie between Fort de Kock and Solok—that is, some miles to the north or north-east of Padang. The brick houses that withstood the earlier shock were destroyed and the number of lives lost is placed at 400. The recent shocks occurred in a district lying many miles to the north-west of that visited by the great earthquake of June 12, 1893, but in a part of the island disturbed from time to time by destructive earthquakes, one of the most important being that of May 17, 1892. This latter

earthquake is of interest, as it was the earliest in which crust-movements were measured by a repeated triangulation of the district. Prof. H. F. Reid, from a study of the displacements (*Bull. Seis. Soc. Amer.*, vol. 3, 1913, pp. 72-79), infers that the movements took place horizontally along a N.N.W.—S.S.E. fault 150 or 200 km. in length, the west side moving to the N.N.W. and the east side to the S.S.E., the total relative slip being 3.5 or 4 metres. The movements, both in nature and amount, bear a close resemblance to those which took place along the San Andreas fault at the time of the Californian earthquake of 1906.

Replying to a question in the House of Commons on July 12, Mr. Ormsby-Gore, Under-Secretary for the Colonies, said that arrangements have been made by the Department of Scientific and Industrial Research for communicating regularly published and other information as to the work done under its auspices to Dominion Government research organisations, to the principal unofficial research centres, and to the Governments of India and the Colonies. In return, valuable information is being received by the Department from the oversea parts of the Empire Similar arrangements for the exchange of information on agricultural research are in force; and it is proposed that a conference on the subject of inter-Imperial co-operation in agricultural research shall be held in the autumn of 1927. Invitations to this conference were issued last year to the Governments of the Dominions, Colonies, and Protectorates.

A memorial tablet has been placed in the Dominion Archives building, Ottawa, in memory of sixteen members of the Canadian Arctic Expedition, 1913-18, who perished during the expedition in widely separated sections of the Arctic. In addition to the inscription "in memory of those who perished, Canadian Arctic Expedition, 1913–18," and the names in alphabetical order with the ranking of each, there is an inscription at the foot of the tablet: "for Canada and for Science—pour la patrie et pour la science." Of the five members of the scientific staff who are thus commemorated, one is a Canadian, son of the late Dr. A. E. Malloch, of Hamilton, Ontario, and a member of the Geological Survey of Canada. Henri Beuchat, anthropologist, was a distinguished writer on American archæology and ethnology from Paris. Bjarne Mamen, topographer of Oslo, Norway, had served on the Norwegian-Spitsbergen Expedition before taking part in the Canadian expedition. James Murray, oceanographer, and Alister Forbes Mackay, surgeon, were from Scotland, and had been with Shackleton in the Antarctic. Peter Bernard, master of the *Mary Sachs*, a native of Prince Edward Island, lost his life, as did Charles Thompson, seaman, while crossing Banks Island in the winter of 1916–17. André Norem, Daniel Wallace Blue and John Jones were buried on the north coast of Alaska, Baillie Island and Victoria Island, N.W.T. After the sinking of the *D. G. S. Karluk*, north of Siberia, in January 1914, four men were lost attempting to reach Wrangel Island over the sea ice: James Murray, Alister Forbes Mackay, Henri Beuchat, and a seaman, Stanley Morris. Another party of four, led by First Mate Alexander Anderson, consisting of Charles Barker, John Brady and Edmund Golightly, seamen, succeeded in reaching Herald Island, but their fate was not known until a whaling vessel calling at the island in 1924 discovered the relics of the party on the beach. George Breddy, seaman, died on Wrangel Island, as the result of an accidental gunshot wound, and George Malloch and Bjarne Mamen, perished from scurvy at Rodger's Harbour, Wrangel Island, in May 1914.

Sir J. C. Bose, of Calcutta, has been giving lectures and demonstrations recently in Great Britain on plant stimulus and response. This is a subject to which he has devoted his energies for many years, and he has devised various delicate instruments for magnifying the minute responses of the plant to stimuli. Plant physiologists have not hastened to take up the use of such instruments, which would surely by their delicacy yield interesting results in the hands of any skilled experimenter. There is still much to learn about plant response, and Sir Jagadis has done useful work in directing attention to the delicacy of the plant as a responding mechanism. In a recent lecture at the Royal Society of Arts he referred to the sensitiveness of the plant to ether vibrations, not only to visible light but also to the ultra-violet and to octaves of long invisible waves. He also referred to the death spasm accompanied by an electric discharge, which he believes to take place when the plant dies but before it begins to droop and wither.

The memory of Benjamin Harrison and his life long devotion to archæology, and particularly to the study of the evidence of man's earliest handiwork in the form of stone implements, will be appropriately preserved as a result of the efforts of the promoters of the "Benjamin Harrison Memorial Fund." On Saturday last, July 10, a tablet to his memory was unveiled in Ightham Church, and as part of the memorial ceremony the title-deeds of the Coldrum Stone Circle at Trottiscliffe, Kent, which has been purchased out of the contributions to the Fund, were handed over to the National Trust. Admirers of Benjamin Harrison, who are many, will be gratified that the preservation of this most interesting relic of early man should be assured, and that it should be associated with the memory of one of the most devoted of the pioneers in archæological studies in England

A letter from Lord Onslow appears in the July issue of *Man*, putting forward a plea for the preservation of specimens of ethnographical interest in Great Britain at present in private hands. It is pointed out that the nineteenth century being primarily a century of settlement, as opposed to the two preceding centuries which constituted the age of discovery, it was pre-eminently the century of the collector, and there must remain in private hands a large number of ethnographical objects which were acquired before their use among primitive peoples had been superseded by articles of European manufacture. If immediate steps are taken, it should be possible to preserve a large number of objects of great ethno-

graphical and historic value, and in many cases to record their history and provenance. The Council of the Royal Anthropological Institute has appointed a committee to explore the possibilities of the situation. Lord Onslow has consented to act as chairman of the Committee.

WE are glad to know that it is proposed to establish a memorial to the late Mr. F. S. Spiers, secretary of the Faraday Society and of the Institute of Physics, to remind future generations of his valuable services to science and human welfare. It is suggested that a memorial lecture, to be paid for out of the interest on the fund subscribed, shall be instituted under the auspices of the Faraday Society. A committee to promote this appeal has been formed, with Sir William Bragg as chairman, and the sum of about 130*l*. has already been subscribed. We are sure that many who have been associated with Mr. Spiers in scientific meetings and the preparation of papers and reports will desire to add to this sum Contributions should be sent to the assistant honorary secretary, Miss M. Parsons, of the Faraday Society and the Institute of Physics, at 90 Great Russell Street, W.C.1. Cheques should be made payable to Prof. A. W. Porter and crossed " F. S. Spiers Memorial Fund A/c."

ARRANGEMENTS are being made by the Regional Survey Association to hold a meeting at Richmond, Yorkshire, on September 1-10 next The district, which is rich in historical associations and natural beauty, will be studied from as many points of view as possible—physical, geographical, historical and social. Lectures will be given by specialists in these subjects, and these will be supplemented by practical work and observational excursions in the neighbourhood. The latter will cover Barnard Castle, Muker and Keld, Leyburn in Wensleydale and Catterick Bridge, localities which will afford exceptionally favourable fields for research. Full particulars may be obtained from the Secretary, Leplay House, Belgrave Road, London, S.W.1.

THE report on the Health of the Army for the Year 1924 has recently been issued (London: H.M. Stationery Office, 1926. 3s. 6*d*. net). Efforts have been made to expedite issue, with the result that this report appears within about four months of its predecessor. A melancholy interest attaches to it, for it is signed by the late Sir William B. Leishman, Director-General, A.M.S The improvement in the health of the troops, noted in previous reports, was maintained during 1924, with the exception that the admission ratio shows a fractional increase over 1924, due to influenza Tonsillitis again caused a large number of admissions to hospital, and middle ear disease heads the list of diseases causing the greatest loss of men through invaliding. Interesting details are given both of the medical measures and equipment employed in the army in the treatment of disease and of the hygienic and other measures now taken to prevent disease and to improve the lot of the soldier.

THE technical programme has now been issued of the sectional meeting of the World Power Conference, to be held at Basle on August 31-September 8 in the halls of the International Exhibition for Navigation and Utilisation of Hydraulic Power. Five broad subjects of discussion have been arranged: (*a*) utilisation of water power and inland navigation, (*b*) exchange of electrical energy between countries, (*c*) relation between the hydraulic and thermal methods of generating electricity, (*d*) electricity in agriculture, (*e*) railway electrification. At the conclusion of the meeting, an official tour of Switzerland will be made, lasting from September 9 until September 12. Communications for the British National Committee should be addressed to the Secretary, World Power Conference, 36 Kingsway, London, W.C.2.

ON May 30, Dr. Truman Michelson, of the Bureau of American Ethnology, left Washington for the reservation of the Fox Indians at Tama, Iowa, where he will study the ritual of the religious ceremonies which are held in the spring and autumn. He will afterwards proceed to Wyoming to study the language of the Arapaho, which appears to be a widely divergent derivative of Algonquin. This is the fifteenth consecutive season that Dr. Michelson has spent among the Fox Indians, from whom he has collected a large amount of anthropological material. Some of this material appears in the latest volume published by the Bureau of American Ethnology, but the greater part awaits publication owing to the lack of funds. This is the more to be regretted as the Fox are a reticent people with an interesting history—they contributed materially to the loss of Canada by the French to the British by breaking up the trade route from Louisiana to Canada—and although they suffered some admixture with European blood in the early days of American colonisation, they have since stubbornly maintained their racial purity.

AN announcement has been issued of the fifth competition, for 1926, for the Patxot prize, which was instituted in 1922, primarily to stimulate research in Catalonia in the physical sciences and mathematics, by M. Raphaël Patxot i Jubert. The prize for 1926 will be 5000 pesetas (present value about 160*l*.), and the jury of award will consist of two specialists and the founder of the prize, who retains rights of publication. Competing works should be addressed to Rue de la Cucurulla, 1 et 3, Barcelona, and must be received by December 31, 1927. They may be in Catalan, any Latin tongue, or English, and the subject is the meteorology of the western Mediterranean, and more especially of the Catalan coast. One competition for 1924 (10,000 pesetas) for a documented monograph relating to the history of the physical sciences or mathematics in Catalonia in the Middle Ages, closes on December 31, 1928. Another prize for 1924 was not awarded, although three memoirs on physiographic studies of Catalonia were entered, for which minor awards were given. The prize for 1925 (5000 pesetas), which closes on December 31, 1926, is for a monograph in Catalan on atmospheric physics applied to Catalonia.

UPON its title page the *Journal of the Royal Agricultural Society of England* bears the Society's distinctive motto "Practice with Science." In view of the latter epithet it is entitled to notice here. Under the heading "Special Articles" there are in vol. 86 eight papers, of which many of the authors bear well-known names either in 'Practice' or 'Science.' The most arresting contribution is one on the "Use of the Dynamometer in Soil Cultivation Studies" by Dr. Keen, of Rothamsted. This gives a summary of the novel results obtained by the use, for the first time, of an instrument of real precision in measuring the draft of tillage implements, the unexpected result being that draft does not necessarily increase *pro rata* (even in linear dimensions) with speed. In regard to tillage problems, however, one may be permitted to suggest (as Wren Hoskyns believed almost a century ago) that the future of economical tillage lies with a rotary implement rather than with the plough, designed, as the latter is, to suit the slow-moving ox or horse. The Oxford Research Institute in Economics contributes a timely article on the sugar-beet position. For the first time in the rather turgid literature on this subject, attention is directed to the fact that the introduction of this crop on any extensive scale necessarily contracts, in a serious degree, the provision of animal food, and consequently raises questions of fundamental economic importance to British farming, dependent as this is, to a pre-eminent degree, on animal husbandry. The Society has recently established a Research Committee, but judging by its present report its title should be, with greater justice, the Field Investigation Committee; for it is almost wholly concerned with interesting and valuable practical trials in such subjects as green manuring, lucerne growing, malting barley trials, grassland improvement, and so forth.

PROF. A. F. VON EISELSBERG, professor of surgery in the University of Vienna, has been awarded the Lister medal, given by the Royal College of Surgeons of England, for distinguished contributions to surgical science.

THE Council of the National Institute of Agricultural Botany has awarded the Snell Memorial Medal for the year 1925 to Dr. R. N. Salaman. The medal is given annually to mark distinguished work in the sphere of potato husbandry, and has been awarded to Dr. Salaman in recognition of his eminent services in the study of the problems connected with the breeding and the diseases of potatoes. The medal will be presented to Dr. Salaman at the public inspection of the trials at the Potato Testing Station, Ormskirk, on August 19.

PROF. CARL DIENER, professor of palæontology in the University of Vienna, has been elected a foreign member of the Geological Society. The following have been elected foreign associates of the Society: Dr. A. L. Day, of the Geophysical Laboratory, Washington, D.C.; Prof. Otto Jækel, professor of geology and palæontology in the University of Greifswald; Prof. Maximin Lohest, professor of geology and physical geography in the University of Liège; and Prof. Pierre Pruvost, professor of geology and applied mineralogy in the University of Lille.

THE Vienna Academy of Sciences has elected as honorary member Dr. Ernst Fuchs, emeritus professor of ophthalmology in the University of Vienna, and the following as foreign corresponding members: Prof. G. H. Hardy of Oxford, Dr. C. V. L. Charlier of Lund, Dr. S. Ramon y Cajal of Madrid, Dr. O. Richter of Brünn. Prizes have been awarded to Dr. A. Franke for his work on the formation and transformation of glycols, and to Dr. G. Stetter for his work on the determination of the masses of atomic fragments. The prize offered at the instigation of Dr. Hans Vaihinger, president of the Philosophical Society "As-if," for an essay on "Fictions in Mathematics" has been awarded to Dr. C. Betsch of Kannstatt, and Dr. M. Draeger of Chemnitz has been highly commended.

THE publication of the *British Journal of Experimental Biology* has been undertaken by the Cambridge University Press. It is the organ of the Society for Experimental Biology, but contributions are accepted from other than members of that body. It is edited by Mr. J. Gray, with the assistance of Dr. F. A. E. Crew and others.

MESSRS. Dulau and Co., Ltd., 34 Margaret Street, W.1, have just issued a useful catalogue (No. 143) of some 1200 second-hand books on phytopathology and horticulture. It is conveniently arranged under the headings: phyto-pathology, fungi, mosses and hepatics, lichens, diatoms and desmids, algæ and plankton, ferns and lycopods, cryptogamia, botany, floras, gardening, herbals, etc.; and agriculture and economic botany.

ANOTHER of Messrs. H. Sotheran and Co.'s well-known catalogues has just reached us. Its number is 800 (or "Catalogue of Science and Technology," No. 111, Part vii.: x. and xi.), and in it are particulars of nearly 4000 second-hand works on chemistry and chemical technology. The classification is as carefully carried out as in earlier parts of the catalogue, and there are the valuable bibliographic details and comments which one looks for in this publication which is of the greatest usefulness to collectors and librarians of scientific publications. Applications for the catalogue should be made to Messrs. H. Sotheran and Co., 140 Strand, W.C.2.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant lecturer in the Education Department of the University of Leeds with, preferably, qualifications and experience in teaching science or geography—The Registrar (July 19). A demonstrator in mathematics at the Royal College of Science, and a demonstrator in mathematics at the City and Guilds (Engineering) College—The Secretary, Imperial College of Science and Technology, South Kensington, S.W. 7 (July 26). An assistant librarian at the University College of North Wales, Bangor—The Registrar (July 26). A lecturer in physical chemistry in University College, Dundee—The Secretary and Registrar, The Uni-

versity, St. Andrews (August 16). A lecturer in zoology at Armstrong College, Newcastle-upon-Tyne—The Registrar (August 28). A principal of the University College of North Wales, Bangor—The Registrar (October 1). A chief science mistress at the County School for Girls, Beckenham; or a temporary post until Christmas and a permanent post in September or January—The Head Mistress (marked 'Science Post'). Directors of propaganda for calcium cyanamide in India and in Ceylon respectively—The Director of Propaganda for Calcium Cyanamide, Adelaide House, King William Street, E.C.4. An assistant entomologist under the Empire Cotton Growing Corporation for work on cotton pests in the Union of South Africa—The Secretary, Empire Cotton Growing Corporation, 2 Wood Street, Westminster, S.W.1. An assistant master at Soham Grammar School to take charge of practical instruction in Nature study, horticulture, and the elements of agricultural science—The Secretary for Education, County Hall, Cambridge.

ERRATUM.—In the issue of July 10, p. 64, col. 1, line 21 of paragraph on "Silver Iodide in Gelatin Iodo-bromide Emulsions": for "440 mm." read "440 $\mu\mu$."

Our Astronomical Column.

FINLAY'S COMET.—Mr. S. Hasunuma, of Tokyo, who has calculated the perturbations of Finlay's comet (*Astr. Nach.* 5453), finds that they delay the perihelion passage until August 7, which is some six weeks later than the approximate value assumed in the B.A.A. Handbook. The effect is to bring the comet into a more favourable position for observation, so that its detection this summer is now quite probable. The following ephemeris for 0^h is based on perihelion August 3·0

	R.A.	N. Decl.
July 18.	3^h $3{\cdot}7^m$	13° 48′
„ 26.	3 40·9	16 38
Aug. 3.	4 16·9	18 56

A change of +4 days in perihelion date diminishes the R.A. by about 10^m and the Decl. by about 90′. The comet must be looked for low in the east just before dawn.

THE COMING PERSEIDS.—The earlier meteors of this famous shower have been perceptible since the opening of July, and it is very interesting to trace the development of the display and the motion of its radiant from night to night through the constellations of Andromeda and Perseus.

This year should provide a shower of more than usually prominent character, for the moon will be new on August 8 and practically invisible at the period of the maximum.

The radiant moves E.S.E. in a line corresponding to 39° north of the ecliptic, and its positions on four dates in July, August, and September are as follow:

		Star near
July 15 . .	15° +47°	Psi Andromedæ
August 1 .	31 +52°	10° N. Gamma Andromedæ
August 15 .	49° +57½	8½ N. Alpha Persei.
September 1 .	69° +61½°	2° W. Beta Camelopardalis.

New observations should be applied to test the accuracy of these approximate positions. The Perseids usually leave streaks, and these are occasionally very enduring in the case of the brighter meteors, so that their directions of flight may be recorded with considerable fidelity.

Some hundreds of the Perseids have had their real paths computed, and there seems little necessity for further data of this sort except on nights near the commencement or end of the display, when double observations will give good and certain radiants. It will be interesting, however, to learn more of the minor contemporary showers. Observers, in comparing one year's results with others, should make such allowances as appear to be required respecting the weather, moonlight, etc. The hours of observation are also important as greatly affecting the altitude of the radiant and the number of meteors distributed.

THE SIMEIS OBSERVATORY REFLECTING TELESCOPE.—The report of the Pulkovo Observatory for 1925 has been published. The most important work done during this year is considered to be the erecting of the 40 inch (1 metre) reflecting telescope at the Simeis Observatory in the Crimea, which is affiliated to the Pulkovo Observatory. The reflector was made at the works of Sir Howard Grubb and Sons, Ltd., and a brief description of it is to be found in NATURE of April 12, 1924 (vol. 113, p. 550).

In the report some interesting details are given relating to the erection of the instrument. The masonry was started on June 6, 1925, and at the beginning of November the mechanical parts of the revolving dome were so far ready that the erection of the reflector could be proceeded with. Finally the large mirror was inserted in its case with great precautions, and was fixed to the tube.

By the end of the year the reflector was mounted, with the exception of the clock-work. Movement of the instrument by hand is easy, although the total weight is 6½ tons. The mechanical parts of the instrument work perfectly, the construction being the highest type of technical achievement.

The programme of research being dependent on the quality of the mirror, a preliminary laboratory test was made during the summer months by Hartmann's method at the centre of curvature of the mirror. The conditions during the test were purposely chosen far from favourable and approximated closely to the average conditions in the dome. Quite apart from the mounting, it is very important to have a thorough knowledge of the shape of the mirror. A series of independent photographs were taken on different days and were examined, in order to get an idea of the mirror's shape. The following details are noteworthy. The results of measurements of different photographs taken on the same day give very nearly the same results. The zonal aberration is exceedingly small, of the same order as the errors of measurement. The average departure in different zones is about 0·03 mm. The accuracy of the configuration of the mirror (departure from a paraboloid) is of the order of $\frac{1}{10}$ of a wave-length. According to Hartmann's classification, the mirror may be considered as "hervorragend gut" (exceedingly good). The results of the analysis leave no doubt that the mirror has a perfect shape, and in comparison with data published for other big mirrors it certainly ranks among the best.

Research with such an excellent instrument on both the mechanical and the optical sides is expected to give good results in the various interesting problems for which the instrument is intended to be used.

Research Items.

RELATIVE VALUE OF FACTORS INFLUENCING INFANT WELFARE.—In Parts 3 and 4 of the first volume of *Annals of Eugenics*, Miss Ethel M. Elderton concludes her exhaustive study of data from Rochdale, Bradford, Blackburn, Preston and Salford on infant viability and summarises her conclusions. These, both positive and negative, are of fundamental importance. The factors, which are shown to be more or less closely associated with viability, are the health of the mother, the health of the baby at birth and, of much less significance, the maturity of the mother and the position of the child in the family. The evidence is conflicting; but in some towns there appears to be a rather heavier death-rate among the infants of women under twenty-three years of age. Miss Elderton has also formed the opinion that there is a higher infant death-rate among the first-born which may be concealed during epidemics of diarrhœa. Association with the habits of the parents and the occupation of the father is small; so is that with all other environmental conditions, *e.g.* poverty, whether judged by the income of the family or the wage of the man, and housing; while no evidence is afforded that children born at the end of a large family suffer in vitality, or that bottle-feeding in itself causes a high infant mortality. Nor, so far as infant mortality is concerned, has indoor sanitation any advantage over outdoor sanitation. The whole trend of the evidence is in favour of the view that the infant death-rate is selective. From the point of view of the race, also, the success of health visitation and inspection is in the right quarter, tending to assist chiefly the better portion of the community. Miss Elderton urges very strongly the need for fuller information to decide whether parental health and habits cause environmental conditions or whether these are responsible for parental health and habits. Much of the available evidence favours the first of these alternatives.

TEARS.—Prof. Maurice Canney, in the *Journal of the Manchester Egyptian and Oriental Society*, No. 12, points out that there is a curious resemblance in birth and death ceremonies which may be due to the fact that birth, marriage, and death all mark a change of state, and the ceremony may be one of initiation into new life. Though it may be natural to express grief by howling, wailing, and weeping, much depends upon how things are done. Though black is sometimes stated always to have been a symbol of death, it seems frequently to have been of life-giving significance, as, for example, in the use of antimony and henna as applied to new-born babes in Egypt. In the case of tears, two ideas have intermingled, but in a civilised community tears are almost exclusively connected with grief and pain, excluding the idea of life-giving, which is really the more primitive. The ceremonial weeping and bawling, which is a feature of mourning ritual in, for example, China, Africa, and elsewhere, clearly has a special significance, its object being not to express grief, but to awaken and reanimate the dead. Tears may be compared to the shedding of blood. The ceremony of cutting oneself for the dead renewed the bond of union with the living. Further, tears being creative, they are potent to produce fertility and ensure good crops. Hence in a number of instances in human sacrifices, the victims are frequently tortured to make them shed tears.

PREHISTORIC EARTHWORKS IN NORTH CARDIGANSHIRE.—A regional survey of the prehistoric earthworks of North Cardiganshire by Mr. I. T. Hughes in vol. 4 of the *Transactions of the Cardiganshire Antiquarian Society* gives a summary description, with plans, of 28 earthworks which can be classified as true 'hill-top' camps. They are confined to a region north of a line drawn from the sea near Llanrhystyd along the Wyre Valley to Trawscoed, then towards Ystrad Meurig and along the valley of the Upper Teifi. There is, however, an important group along the Aeron Valley. North of the Wyre—Upper Teifi line they are isolated from the camps of western Montgomeryshire by the Plynlimon Range. No camp is below the 300 ft. contour and four are above the 1000 ft. range. The upward limit of camps coincides with that of cultivation and modern habitation. Some of the camps are situated in proximity to the sea and defend inland routes, and the distribution suggests that Llanrhystyd was a port of some importance, probably connected with the south coast of England by the conjectural Bronze Age route Southampton—Harlech with a branch from Evesham, "aiming probably at Aberystwyth or some port south of that town." The chief metalliferous areas of Cardiganshire are characterised by groups of camps. Place names associated with the camps near the sea, the valleys and the mining areas suggest Irish affinities which are supported by finds of a halberd, a flat celt, and a palstave of Irish design. The camps, therefore, would appear to be the centres of a community of Goidelic lead lords with close connexions with Ireland. Without the evidence of the spade it would be unwise to offer an opinion as to their age

SOIL PROBLEMS IN COTTON GROWING IN THE SUDAN.—The Sudan Government has published (Khartoum, January 1926) the report of a meeting of the chemical section of the Wellcome Tropical Research Laboratories, held at Wad Medani, in which the problems of cotton-growing in the Sudan Gezira were passed in review from the point of view of chemist, physicist, and biologist. This review is particularly noteworthy on account of Dr E. M. Crowther's discussion of the effect of the nitrogen supply It appears that, after the water supply, the most important soil factor in the Gezira is the nitrogen supply. Cotton cultivation in the Gezira in this respect shows an essential difference from the conditions prevailing in Egypt

OXYGEN REQUIREMENTS OF FISH.—Data have been presented concerning the oxygen requirements of different kinds of fish at various temperatures by J. A. Gardner (Min. of Agric and Fisheries Fishery Invest., Ser. I. vol. 3, No. 1, 1926: Report on the Respiratory Exchange in Freshwater Fish, with Suggestions as to Further Investigations. Pp. 17. London: H.M. Stationery Office, 1926 2*s.* net). At ordinary limits of temperature, the respiratory quotient varies between 0·6 and 1, but the majority lie round 0·8. Trout appear to be more sensitive to rise in temperature than the coarse fish examined. Even 25° C proved fatal to a large trout, though smaller specimens could be acclimatised to stand 25° for some hours. Goldfish can endure 30° C., but not 35° C.

ASIATIC AND AMERICAN ELEMENTS IN THE LEPIDOPTERAN FAUNA OF POLAR EUROPE.—The well-known Russian lepidopterist Prof. N. I. Kuznecov has been working for many years on the problem of the distribution of lepidoptera in the Polar regions. While a comprehensive work on the subject is in preparation, he publishes some preliminary results of outstanding interest (*Comptes rendus Acad. Scien.*, Leningrad, 1925). Many species of butterflies are characterised

by a discontinuous distribution, being present in polar Europe and in eastern Siberia, but not occurring in the wide area between the Yenisei and the Ural Mountains. This area, corresponding to the West Siberian plain, can only be explained by the West Siberian Sea, which existed in the Oligocene and extended as far southwards as the Aral Sea. This means that the age of the European circumpolar faunal elements, as well as of the Holarctic ones, must be estimated in any case as pre-glacial, or, more precisely, as pre-oligocenic. These pre-oligocænic circumpolar elements are probably autochtonous, which leads to the conclusion that the Arctic faunistic region may be considered as independent of the Palæarctic region. On the problem of possible origin of these ancestral Holarctic elements, which since the Palæogenic times have populated the whole northern zone of both Eurasia and America, Prof. Kuznecov is of the opinion that they originated in the Angaro-American continent, which embraced eastern Siberia and north western America down to Colorado and the Great Lakes, stretching westwards across northern Siberia to the White Sea.

MEDITERRANEAN STERNOPTYCHIDÆ.—Messrs. P. Jesperson and A. V. Tåning (" Report on the Danish Oceanographical Expeditions, 1908–1910, to the Mediterranean and Adjacent Seas." No. 9, Vol. 2 (Biology). A. 12 : " Mediterranean Sternoptychidæ," by P. Jespersen and Å. Vedel Tåning. Copenhagen: Andr. Fred. Høst and Søn, 1926. 35s.) continue the systematic account of the fishes belonging to the Sternoptychidæ taken by the Danish Oceanographical Expedition in 1908-1910 under the leadership of Dr. Schmidt. Together with Jesperson's previous report in this series on the genera Argyropelecus and Sternoptyx (Reports, vol. 2, A. 2), it forms a valuable account of the post-larval, adolescent, and where necessary, of the adult stages belonging to the species of this family occurring in the Mediterranean Many cases of doubtful synonymy are cleared up and a new species of the genus Cyclothone described. Much attention is given to the comparison and identification of the species, and numerous clearly executed figures accompany the text; maps are also given showing the horizontal distribution for each species. The information relating to seasonal, diurnal, and ontogenetic vertical migrations, as well as that relating to the horizontal distribution, is interesting and important. Very young larval forms seem not to have been found except in isolated cases; this being due in the authors' opinion to their small size and delicate nature, and to their destruction by the net. Post-larval forms are generally taken close to the surface, whilst typical metamorphosis stages are found in much deeper water, mainly from 500 to 1200 m w., depending upon season and geographical locality, and varying for each species; it seems, moreover, that the change in depth of living takes place suddenly, as intermediate stages have not been found at intermediate depths. Diurnal vertical migrations are undertaken by most of the adults, and, generally speaking, they are higher in the water in the summer than in the winter.

BIOMETRIC WORK ON VARIABILITY.—The *Izvestia Buro po Genetik i Eugenik*, No. 4, recently issued by the Russian Bureau of Genetics and Eugenics, contains five biometrical studies on variability, with short summaries in English or German. The longest paper, by Prof. J. Philiptschenko, on the variability of quantitative characters in twelve pure lines of soft wheats, considers the conditions under which relative values or indices are more suitable than absolute values for certain measurements. The resulting correlations are classified as (1) intrabiotypic, depending on reaction-norms within a biotype; and (2) intrapopulative, depending on the relations of the biotypes within a population. T. Liepin, in a study of variability in a Chrysomelid beetle, *Phædon cochleariæ*, finds by measuring larval stages that the variability gradually decreases with age, this decrease being due to internal factors, while unfavourable conditions are shown unexpectedly to cause increased variability. G. Pchakadze finds in *Daphnia pulex* that the young from fertilised eggs are nearly twice as variable as those from parthenogenetic eggs. He also claims that adult parthenogenetic Daphniæ are more variable than adults from fertilised eggs, and that while variability decreases with age in Daphniæ from fertilised eggs, it increases with age in parthenogenetic individuals. D. Diakonov shows briefly that bimodal variation need not necessarily mean genetic dimorphism. A. Zuitin deals with similar problems of variability in the grasshopper, *Dixippus morosus*, which is also parthenogenetic. He finds a decrease of variability during post-embryonic development, but concludes that if environmental conditions overbalance the internal regulatory processes within the animal, an increase of variability with age may result.

SOME PERIODS IN AUSTRALIAN WEATHER.—A discussion, by Dr. Edward Kidson, Assistant Director, Commonwealth Bureau of Meteorology, is published by the Bureau of Meteorology, Melbourne, Commonwealth of Australia, as Paper 1—extract from Bulletin No. 17. Mr. Hunt, the Commonwealth Meteorologist, in the introductory note states that Dr. Kidson has put into more precise form much that has for many years been common knowledge to Australian meteorologists, and he considers the discussion should lead to an advance in our knowledge of meteorological processes in the Australian region. The author has dealt with weather charts for more than thirty years. The close relationship shown between the annual latitude range of anticyclones and the Wolfer sunspot numbers is one of the results.

EARLY POLARISATION APPARATUS.—The issue of *Die Naturwissenschaften* for May 28 contains over the signature Kpl. an illustrated account of an apparatus for investigating the polarisation of light by reflection shown by J. Tobias Mayer to the Gesellschaft der Wissenschaften of Göttingen on November 21, 1812. It consisted of two parallel glass plates the back surfaces of which were blackened; the upper one received sunlight and reflected it vertically downwards to the second, which could be rotated about a vertical axis. It was, therefore, the apparatus now known as Norremberg's, although there appears to be no record of Norremberg having constructed his apparatus before 1842. Mayer's paper will be found in *Commentationes Soc. reg. scien. Göttingen*, 1813, No. 9.

THE ATOMIC NUCLEUS.—The most recent of the suggestions as to the constitution of the atomic nucleus is that made by S. Ono in the April issue of the *Proceedings of the Physico-Mathematical Society of Japan*. He suggests that the nucleus consists of two parts, an inner and an outer. In the inner portion each proton or positively charged elementary particle is accompanied by an electron, while in the outer part each pair of protons has an electron. The volume occupied by the outer combination is on the average 1·1 times that occupied by the inner, and the combinations are uniformly distributed, the inner through the volume of a sphere, the outer through the shell surrounding the sphere, its outer radius

being on the average 0·6 times the diameter of an outer combination greater than that of the sphere. On this supposition the relation between the atomic numbers and the atomic weights of the heavier elements comes out in close agreement with the facts, but the number of possible isotopes is in excess of those found. Two groups projected from the outer nucleus constitute an α-ray, and the disturbance of the equilibrium of the atom results in the emission of two electrons from the rings outside the nucleus —the β-rays, which it is known are emitted in pairs.

Protection against Ignition by Perforated Plates.—It is rather astonishing to read of and more astonishing to see red flames—several inches in height—emerging through perforations in a metal plate into an explosive mixture of gases without igniting the mixture. Nevertheless this may be seen in the laboratories of the Safety in Mines Research Board at Sheffield, and the description of the experiments may be read in the second report on flameproof electrical apparatus with perforated-plate protection (Mines Department: Safety in Mines Research Board. Paper No. 21: Flameproof Electrical Apparatus for use in Coal Mines. Second Report: Perforated Plate Protection. London: H.M. Stationery Office, 1926. 1*s.* 3*d.* net). Messrs. Wheeler and Grice have shown experimentally that by allowing the escape of burning gases (produced by the explosion of fire-damp and air in a bomb) through suitably spaced holes in a metal plate, the escaping gases—still visibly burning—may be so cooled down by conduction and expansion as to be incapable of igniting a 10 per cent. methane-air mixture surrounding the bomb. When two suitably perforated brass sheets, such as are manufactured commercially, are superposed—with a small interval between them—as part of the cover of a switch-box, an explosive methane mixture can be fired inside the box without igniting a similar mixture outside.

Combustion under direct Electrical Discharge. — In an interesting paper published in a recent number of the *Proceedings of the Royal Society*, Messrs G. I. Finch and L. G. Cowen describe their experiments on the combustion taking place when a direct discharge is maintained between metallic electrodes in electrolytic gas at pressures between 20 mm. and 100 mm. of mercury. In the inflammation of gases there is a pre-flame period of slow combustion when chemical combination begins; this process usually increases automatically in intensity until the normal flame appears. But it is possible to maintain the flameless regime under special conditions. Some twenty years ago, Kirkby found that when a direct discharge was maintained in electrolytic gas under low pressures, the water formed (without flame) was proportional to the quantity of electricity passed, and that the combustion was independent of the nature of the electrodes and occurred at all points of the discharge. Later workers have chiefly studied ignitions by high-tension discharges from a coil or by capacity-discharges from a condenser. The present authors have sought to eliminate so far as possible all 'capacity' effects, and to maintain a perfectly steady discharge with a glow free from striations and flickering—so that the combination might be related only to ionisation and not be due to high temperature. Under the conditions maintained by the authors, the rate of formation of water was found to be directly proportional to the current. By limiting the current, the combination may be confined to the glow round the cathode, when it is independent of the gas temperature and pressure, but varies with the nature of the electrodes.

Direction Finding by Radio.—The Department of Scientific and Industrial Research has just issued the third part of the report on the variations of the apparent bearings of radio transmitting stations. This report gives the results of observations carried out by Dr. Smith-Rose between November 1922 and March 1924 on ship and shore transmitting stations. (Department of Scientific and Industrial Research: Radio Research. Special Report No. 4: Variations of Apparent Bearings of Radio Transmitting Stations. Part 3: Observations on Ship and Shore Transmitting Stations, November 1922-March 1924. London: H.M. Stationery Office, 1926. 2*s.* 6*d.* net.) The previous report describes observations using wave-lengths varying from 2000 to 9000 metres. In the experiments now described, special attention was given to a wave-length of 450 metres as this was the length in general use for every day direction finding during this period. Two land stations were mainly used for the test, the Admiralty station at Orford on the east coast of England and the Radio Research Board's station at Slough. Tests were also made on board ship. It was observed that with the short wave-length of 450 metres there was a tendency for the occurrence of 'blurred' minima which annoy observers. From the point of view of navigation an important result was proved. It was found that the existence of fog had little or no effect in producing errors. On one occasion in particular, although the fog was spread over Great Britain and a large portion of western Europe, yet the directional effects showed only the usual day and night variations. As it is chiefly during foggy weather that direction finding stations are called into action, this result is most satisfactory. Again, when the weather was cloudy and overcast, no special phenomena were noticed. It seems probable therefore that the cause of the variations is not due to any effects produced by solar radiation on the lower strata of the earth's atmosphere. The report concludes by reference to two recent papers communicated by the author and Mr. Barfield to the Royal Society. In one of these a direct determination of the effective conductivity of the earth is made at radio frequencies. This result is of importance in the general study of wave propagation. In the other and later paper, it is stated that some of the radio waves have travelled through the upper regions of the earth's atmosphere before reaching the detector.

Translucency of Porcelains.—With the view of the improvement of the ceramic industry in the United States, an investigation of the causes of translucency has been carried out by Messrs. C. W. Parmelee, professor of ceramic engineering, and P. W. Ketchum, research assistant in the University of Illinois, and the results are given in Bulletin 154 of the Engineering Experimental Station. The measurements of translucency were made by eye with the aid of a Lummer-Brodhun photometer or by the use of a photo-electric cell, the current from which when illuminated was measured by the change of deflexion of an electrometer. The two methods give relative values in fair agreement with each other, although owing to the reddish colour of the transmitted light the absolute value of the translucency by the cell method is less than that obtained by photometer. Increase of thickness of the specimen decreases the transmitted light in the usual exponential way. High felspar content produces high translucency, while flint has a less marked effect in the same direction. High clay content diminishes translucency. Fine grinding of the constituents raises the translucency in a striking way, and increase of firing temperature produces a further improvement.

Studies in Eugenics and Human Heredity in South Africa.[1]

THESE two papers by Dr. Fantham are welcome evidence of the earnestness with which he is pressing home the social applications of biology in the country in which his lot is cast. Whilst they reiterate to a large extent principles that are well known to readers of NATURE, these principles are exemplified by some interesting original observations made by Dr. Fantham since he began residence in South Africa.

The ultimate aim of zoological science is of course a thorough knowledge of the inner nature of animal life. The intense interest of this aim provides the spur which urges to zoological research in old countries like Great Britain, in which Nature has been thoroughly dominated and tamed, and in which we have to be up and doing if any traces of really wild Nature are to be allowed to persist. But in newer countries like the outlying portions of the British Empire the battle with circumambient wild Nature is at its height, and the ultimate victory is by no means assured, and so the light which zoology (and other sciences) can throw on the conditions which are likely to lead to success in this struggle contitutes their main passport to popular favour.

Now there are two main problems for eugenists which emerge from the study of human heredity; one of these may be described as the problem of the Mendelian recessive; this problem is ubiquitous, and it is this question which especially faces social workers in Great Britain. The other is the problem of the crossing of different races: this, usually denominated miscegenation, is the really burning question in countries like South Africa and the United States of America. It would constitute a problem in Australia, also, had not the Australians adopted one particular solution of it which certainly is effective so long as it is maintained, but their power to maintain it for an indefinite period of time is, to say the least of it, exceedingly doubtful. It seems to us that Dr. Fantham has not kept these two problems sufficiently distinct in his mind, for we are convinced that they are entirely different in their nature The term "Mendelian recessive" is meant to denote those defective individuals, constantly turning up amongst modern civilised men, whose defective characteristics are transmitted to posterity in a way which suggests that their inheritance follows the laws of Mendel.

The defects are, however, by no means always recessive. In fact, it seems to us that the importance of the contrast between dominant and recessive characters has been greatly exaggerated by Mendelian writers. What is usually termed a 'mutation,' that is, a sudden divergence from the type, almost always shows a peculiar character which bestows on these 'mutations' a family likeness wherever they may occur. This character is a constitutional weakness as compared with the type, and the question of dominance and recessiveness is merely the question of whether the weakness is or is not sufficiently marked to make itself felt in the F_1 generation where it enters the germ from one side only of the house. These defects show themselves in external marks of the most varied kind, such as brachydactyly (the shortening of the digits accompanied by the fusion of two of the joints), polydactyly (extra toes and fingers), hæmophilia (inability of the blood to clot), night-blindness (loss of the power to see in the dusk), and, most important of all, defective development of the brain or feeble-mindedness. Dr. Fantham quotes some well-known pedigrees, but he also gives examples from his own observations of the inheritance through three generations of such defects as 'stiff fingers' (orthodactyly), permanently bent little finger, premature baldness on the crown of the head, white forelock, and supernumerary thumbs. The inheritance of this last case is very instructive, for the trait was first noted on the left hand and it appeared in the next generation on the right hand. This shows that the character was not due to a 'gene' or 'factor' which initiated an extra growth at a particular place, but to an interference with the normal processes of growth, and there is a strong suspicion that this interference was a too tightly-constricting amnion in the latest stages of development which impinged on and split the thumb rudiment into two.

The social detriment due to the breeding of the feeble-minded of course far outweighs in importance the minor detriments due to the transmission of the slighter constitutional defects. The more extreme cases are confined in asylums, but the less marked cases are at liberty and constitute the lowest stratum in society. They have just sufficient intelligence to secure intermittent employment in the least skilled occupations, though they are in frequent need of poor law relief; they often marry improvidently and reproduce recklessly, for they have no foresight or control of their passions. They give birth to numerous illegitimate offspring, and their children inherit their defects In former times these children, defective in nature and badly cared for, died like flies; now modern philanthropy steps in to preserve them, they increase in numbers, contaminate the race, and are a danger to future generations. Dr. Fantham relies implicitly on this point on the results of the American workers Davenport and Goddard, Estabrook and others Whilst these results in broad outline will doubtless prove to be correct, it is fair to add that they have been severely criticised. Feeble-mindedness is not a definite thing due to a 'factor'; it is a varying grade of germ-damage the origin of which is due to definite causes which ought to be more closely investigated. It is instructive to note that Tredgold has found that feeble-mindedness in a given generation is often preceded in the parental generation by milder symptoms such as epilepsy or even merely nervous instability.

Turning now to the question of miscegenation, we find that the hybrids between two different races such as the Kaffir and the Dutch show no evidence of clear and sharp segregation such as is found when a mutation is crossed with the type. These hybrids show combinations of the qualities of the parental races in every conceivable proportion, but the attempt to analyse these qualities into factors, when pushed into details, reveals itself as impossible, as we have previously pointed out in the pages of NATURE. The qualities of races are acquisitions won in the struggle with the environment, and they constitute an epitome of the evolutionary history of the race. Dr. Fantham points out that the negro race, left to itself, shows no tendency to produce a civilisation or indeed to undergo any progressive evolution whatever: that it is deficient in foresight and providence, and exhibits lack of persistence and initiative. The negro is in fact a tropical animal, evolved amidst the teeming life of the warmer and more fertile zones of the earth's surface; clothing is a superfluity, and the means to satisfy hunger are comparatively easily procured, and his qualities correspond with this environment. The Dutch and English are offshoots of the white Nordic

[1] "Heredity in Man: Its Importance both Biologically and Educationally," and "Some Factors in Eugenics, together with Notes in some South African Cases." By Prof. H. B. Fantham, University of Witwatersrand, Johannesburg. *South African Journal of Science*, vol. 21, 1924, and vol. 22, 1925.

race, which grew up under the cloudy skies and cold raw climate of the shores of the North Sea in post-glacial times. The members of this race had to develop boldness and perseverance to survive at all, and they won their food as a result of terrific struggles with the elements, and to this struggle they owe their good and forceful qualities. Dr. Fantham points out that hybrids between the two races lose the admirable qualities of the white and yet are not controlled by the tribal conventions of the negro. Further, as children of the same family differ in the colour of their skins, the whiter consider themselves European and despise their darker brothers and sisters as negroes. Dr. Fantham traced one such hybrid family through five generations. A joint meeting of the Eugenic and Anthropological Societies of London was told last spring that miscegenation was far more widespread than one would gather from Dr. Fantham's papers, and was slowly undermining the moral stamina of the whole of the white population of South Africa. What are known as 'coloured people,' that is, hybrids of the second and third generation, are increasing in number, and the whiter individuals are intermarrying freely with the pure white population. We can only say that we trust that this view is an exaggerated one.

Dr. Fantham alludes to another matter of great importance, namely, the exhausting and weakening results of too frequent pregnancies not only on the mother but also on the children. We ourselves believe that the most fertile cause of human 'mutations' is to be found here. Dr. Fantham gives an example of the results of such pregnancies traced through three generations. In all three 'Mongolian idiots' appeared; this defect appears to be due to amniotic pressure on the developing brain.

Dr. Fantham's final conclusion is one which we can heartily endorse; it is that "the principles of animal [including human] biology put forward in simple interesting language and illustrated by living examples should form an essential short course in the curriculum of every University student as well as of every school child." This proposal has been pressed on our own Ministry of Education by the Council of the Eugenics Education Society, and when population and cognate problems in Great Britain become sufficiently acute to cause widespread discomfort, it will doubtless be given official attention. E. W. M.

Research in Illumination.

A SURVEY of the work of the Illumination Research Committee of the Department of Scientific and Industrial Research is given in a report issued recently by the Department. These investigations were also reviewed in a paper read by Mr. J. W. T. Walsh before the Illuminating Engineering Society on June 1. In the introduction to the Report the events leading to the formation of this committee are recalled, and attention is directed to the demand for information on lighting matters that has arisen since the formation of the Illuminating Engineering Society in 1909. On the Illumination Research Committee the medical and architectural professions are represented, and there are several members who are experts on illumination and also members of the Illuminating Engineering Society, the various British Engineering Standards Association committees, and other bodies concerned in research on illumination. Co-ordination of effort is thus facilitated and overlapping of work avoided.

The representation of the Medical Research Council on the committee is of special importance, as numerous problems before the committee have a physiological basis. This applies particularly to the study of 'glare,' and of the relation between intensity of illumination and speed and accuracy of fine work. Such fundamental researches necessarily require time. In connexion with the second problem, attention has first been devoted to printing as an example of 'fine work' readily adapted to investigations of relations between illumination and output. In this investigation valuable aid has been rendered by the Joint Industrial Council for the Printing Trades of the United Kingdom. The results are to be presented in a detailed report, but it appears that the relation between illumination and quality of work has been fully substantiated. This investigation will be extended to other forms of 'fine work.'

Other fundamental researches include a comprehensive record of daylight-intensities, now being made at the National Physical Laboratory, Teddington.

Among the 'special problems of urgency' may be mentioned the investigations of enamelled iron reflectors, which have contributed greatly to the framing of the recent British Engineering Standards Association's specification for reflectors used in industrial lighting. The design of picture galleries with the view of the avoidance of troublesome reflections in the glazed surfaces of pictures has also been studied. Another series of researches deals with the effect of flickering illumination on vision and the brightness of glassware used in various lighting fittings (the latter another problem with which a B.E.S.A. committee is concerned). A series of experiments is in progress with the object of studying the effect of colour and distribution on the degree of comfortable illumination required for clerical work. The systems examined include: (*a*) Semi-indirect lighting with vacuum lamps; (*b*) Semi-indirect lighting with artificial daylight (blue bulb) lamps; (*c*) Artificial window lighting with vacuum lamps; and (*d*) Artificial window lighting with artificial daylight lamps. Numerous other investigations include the examination of transmission of light through window-glass, the effect of window size and the reflecting power of walls and ceilings, the relation between glare and visibility in street lighting, and the distribution of temperature in the glass and other parts of lighting fittings.

Mr. Walsh, in the concluding portion of his paper, mentioned that these investigations would be the subject of individual reports, to be issued by the Department in the near future. At the meeting on June 1, general recognition of the importance of the work being done by the committee was expressed. Mr. C. C. Paterson (chairman of the Illumination Research Committee), in opening the discussion, alluded to the services rendered by the Illuminating Engineering Society and its hon. secretary (Mr. L. Gaster) in paving the way for the creation of the committee and initiating these researches. Sir John Herbert Parsons, who presided, emphasised the important field presented for physiological study by artificial lighting, and commended the subject to the notice of ophthalmologists. Miss Wiggins mentioned examples of the valuable aid which the committee has rendered to the British Engineering Standards Association in connexion with its various investigations. Mr. J. S. Dow, in commenting on the relation between illumination and ease of work, pointed out that discretion is necessary in attempting to derive standards on the basis of natural illumination, and suggested that investigations should be directed to the effect on vision of the differences in the spectra of artificial illuminants and daylight. Mr. W. C.

Raffé suggested various inquiries bearing on the effect of colour, and the influence of light on certain metals. Mr. A. Cunnington referred to problems arising in connexion with the passage of railway trains through short tunnels, as illustrating the liability of temporary dazzling of the eyes to cause accidents. Mr. P. J. Waldram discussed the problem of avoiding troublesome reflections in picture galleries, referring particularly to the effect of badly placed skylights.

At the end of the discussion Mr. L. Gaster explained the interlinking of the Illumination Research Committee with the various other organisations interested in research on illumination, and pointed out that the Illuminating Engineering Society is performing valuable service by acting as a 'liaison officer' and as a clearing-house for information. The recent discussion before the Society of the specifications of the various B.E.S.A. committees (see NATURE, March 13, p. 397) proved valuable in making them more widely known, and it is hoped that the discussion of this preliminary report of the Illumination Research Committee would be equally useful. It is of obvious importance that reports of such work should receive the widest publicity and should be thoroughly discussed, and he hoped that the forthcoming reports on individual researches would be likewise presented at meetings of the Society for full consideration.

Primitive Time Reckoning and the Calendar.

THE stages by which the Julian calendar as a method of time reckoning was attained are demonstrated by Dr. Martin P. Nilsson in a contribution to vol. 39, pt. 6 of *Scientia*, which surveys the various methods of measuring time employed by primitive and early peoples, and shows how the conception of a continuum in time, which is the essence of a calendar, has gradually developed.

The mind of primitive man, being essentially interested in the concrete, expresses time in terms of action, such as the time it takes to cook a bowl of rice, or the duration of a journey, the double hour of the Babylonians being an example of the latter. In the early stages certain recurrent natural phenomena are regarded, not as units of time of a certain duration, but as indications of time The conception of continuity is absent at this stage. Thus time of day is indicated by the natural divisions—dawn, twilight, sunrise, or the position of the sun. Night is regarded as a whole. The crow of the cock is employed generally, but few make use of the stars as did the South American Indians and the Homeric Greeks. The conception of a 24 hours' day is late.

In the same way, the season of the year is indicated by natural phenomena, winter, summer, the season of snow, rain, drought. Neither the duration of the season nor, more remarkable, their number, is uniform. While we have four seasons, other peoples have two, three, five, or six. The unity of the year is established only slowly, and that empirically. As among the Banyankole, the reckoning may be from rains to rains. An agricultural people employs the agricultural operations, reckoning from sowing to harvest, the vacant period following the latter not counting.

The year is recorded and identified by some striking happening such as the "year of the meteorites." The Roman method of identifying it by the Consuls is another example.

The observation of the stars and constellations, and especially their heliacal rising, gives a more exact method of time reckoning. These observations are brought into relation with agricultural operations. This leads to the observation of the solar year, which in Egypt was fixed so far back as the prehistoric period through observation of the heliacal rising of Sirius; but the conception of units of time and time as a continuum arose from observation of the moon's phases, which gave the lunar month and the divisions of the lunar month as a record of time within the month. These months were named from the appropriate activities or natural phenomena. Owing to the disparity of the lunar month and the solar year in this luni-solar year, which was known to the Greeks, Babylonians, and Jews, it became necessary, whether the cycle consisted of 12 or 13 lunar months, to employ the principle of inter- or extra-calation, either at irregular intervals or periodically, as was done in Greece in the 7th century B.C. It was this last type of calendar which was superseded by Cæsar's reform, which based the Julian calendar solely on the solar year, recognising the impossibility of equating it with the lunar year.

The Need for Precision in Botanical Terminology.

IN his presidential address to the Linnean Society on May 27, Dr. A. B. Rendle referred to the work of the Society during the year. An interesting feature of certain of the discussions has been the tendency to get back to first principles or definitions and to discover that that which we had regarded as definite is after all vague. For example, in one of the discussions various authorities were quoted in support of different ideas as to the conception of the term carpel. Morphological terms originate in a desire to express certain conceptions, limited or general, and morphologists are apt to find themselves in the same position as the present-day systematist in typifying species. In the matter of definitions a meaning may be attached to a term which the originator never meant to convey; moreover, a vague use of terms may engender vague ideas of relationship. The advisability of the inclusion of the seed-like organs of Pteridosperms under the definition of seeds was also questioned. What is the degree of importance of the differences between the modern seed, which has priority for the use of the term, and the organ characteristic of Pteridosperms? Has the latter advanced beyond the gametophyte stage? Does the fact that postponement of embryo-formation until after the freeing of the seed occurs, for example in Cycads, meet the objection? This absence of an embryo may be called negative evidence; but is it not rather the absence of the criterion of the normal seed, which is an arrangement for the protection of the new sporophyte during a period of rest or transport? The phases in the life-history preceding and accompanying germination must have been widely different in the two great groups.

Until the Caytoniales were described we were clear as to what we understood by Angiosperms. We know nothing of the contents of the seed-like bodies in this primitive group, but we recognise the Angiosperm idea and associated with it the generally considered advanced character of wind-pollination.

Are we clear as to our ideas of what constitutes a Gymnosperm? The tendency is to include here

everything with a seed or seed-like structure which is not angiospermic; that is, everything from Pteridosperms to Conifers—an aggregate of widely differing groups. We are in danger of introducing merely a physiological or biological character into our systematics and of recognising a mixed group which is not comparable with the well-defined group of Angiosperms.

The relationship of Monocotyledons to Dicotyledons has been the subject of many discussions in recent years. Henslow derived Monocotyledons from Dicotyledons as a result of adaptation to an aquatic habit, and Miss Sargent similarly derived them, but looked to the geophytic habit for the explanation. Neither view will withstand criticism, and it is more in accordance with our present knowledge to admit that there is no evidence of the derivation of one from the other. The problem of the origin of these two great subdivisions of Angiosperms, like that of the Angiosperms themselves, and even of modern seed-plants, still awaits solution. We need more spade-work and more facts before we are able satisfactorily to solve these problems of phylogeny.

University and Educational Intelligence.

ABERDEEN.—At the summer graduation the honorary degree of LL.D. was conferred, among others, on Prof. F. W. Oliver and Prof. T. B. Wood.

The degree of D.Sc. has been conferred on J. E. Humphries for a thesis on "Studies in Phenylhydrazones."

CAMBRIDGE.—The Frank Smart Prizes for botany and zoology have been awarded to D. J. Watson, Downing College, and to H P. Hutchinson, St. John's College, respectively. At King's College, E T. S. Appleyard, G. P. Hudson, and J M. Stephens have been elected to research studentships.

MANCHESTER.—On July 8, on the occasion of his retirement from the Beyer chair of zoology in the Victoria University, Prof. Sydney J. Hickson was presented with a cheque by Sir William Boyd Dawkins, on behalf of a number of his former students, colleagues, and friends. In eloquent terms Sir William Boyd Dawkins referred to Prof Hickson's services to science, to the work which he has done for the University, and for the cause of education in natural science. A dinner has been arranged in his honour at the University Refectory on Friday, October 29, when his friends will have an opportunity of meeting him.

MR. GEORGE PATCHIN has been appointed Principal of the Sir John Cass Technical Institute in succession to Dr. C. A. Keane, who has retired.

MR. P. L. ROBINSON, lecturer in chemistry in Armstrong College, Newcastle-upon-Tyne, University of Durham, has been awarded the degree of D.Sc. in the University of Durham for a thesis entitled "A Comparison of the Atomic Weights of Silicon from Various Sources."

ON Thursday, July 8, H R.H The Prince of Wales visited Merchant Taylors' School to lay the foundation stone of a new science building on the north side of the School quadrangle and opposite the opening from Charterhouse Square. The Prince referred to the long and illustrious history of the School and to the great munificence of the Merchant Taylors' Company in fostering its many activities. After the ceremony, Mr. G. N. Pingriff (chief mathematical and science master), Mr. L. H. Hutton (chief modern languages master), and three senior boys were presented to the Prince. The new building will provide for a very complete extension of the science teaching. The old science block contains an exceptionally well equipped, though somewhat cramped, physics laboratory as well as a rather old-fashioned chemical laboratory and biological department. The new building will comprise, on the ground-floor, a large lecture room, a preparation room, and a laboratory workshop; on the first floor, a good laboratory for mechanics and elementary science, as well as a form-room for the 'Special' Fifth; and on the second floor, a new biological department consisting of laboratory and museum. This will enable the old building to be devoted almost exclusively to chemistry and more advanced physics, but the 'Special' Sixth form-room will remain here. Provision will be made for the projection of kinematograph films and a complete electrical installation consisting of an ordinary alternating current lighting circuit, a power circuit for heating and motors, and a 24-volt direct-current circuit for electrolytic and other work.

MANCHESTER was the earliest of the modern universities successfully to adopt the idea of residential halls, and the oldest of these, Dalton Hall, was founded by the Society of Friends in Manchester in 1876, being named after John Dalton, for forty years a prominent Manchester citizen and member of the Friends' Meeting. On July 9 a jubilee dinner was held at the Hall, at which was present a large and distinguished company. The toast of Dalton Hall was proposed by Sir William Boyd Dawkins, who paid a warm tribute to the part played by the institution in the general educational system of Manchester and the breadth of view which inspired its founders and had characterised its life In the great work accomplished by the University, the Society of Friends has rendered inestimable service They had introduced into Manchester a non-sectarian spirit and a sturdy uprightness the value of which was incalculable. Two old Principals of the Hall were present as well as the present Principal, Mr. G. A. Sutherland, until recently senior lecturer in physics at University College, London, all of whom replied to the toast Reference was made to the number of eminent men of science and letters who have passed through the Hall as students. These include Prof. A. S Eddington, Dr G. C Simpson, Dr Gilbert Fowler, Prof. W. A. Bone, Prof W. B Anderson, Dr. Bevan Lean, Sir Michael Sadler, who resided at the Hall when on the University staff; Prof. J. F. Thorpe and Prof. Andrew Robertson, old Hall tutors; and Mr. W. H. Moberley, the Vice-Chancellor elect of the University. The Hall has now accommodation for 65 students and a staff of twelve tutors, most of whom hold or have held appointments on the University staff.

THE Royal Commissioners for the Exhibition of 1851 have made the following appointments to Senior Studentships and Overseas Scholarships for 1926:—*Senior Studentships:* Dr. A. J. Bradley (University of Manchester—crystallography); Dr. H. J. Emeléus (Imperial College of Science and Technology—inorganic chemistry); Mr. R. G. J Fraser (University of Aberdeen—physics and chemistry); Dr. C W. Shoppee (University of Leeds—organic chemistry); Mr. W. L. Webster (University of Cambridge—physics). *Overseas Scholarships:* Mr. R. C. Robb (Dalhousie University, Halifax, Nova Scotia—biology); Mr. F. H. Yorston (McGill University, Montreal—organic chemistry); Mr. H. M. Cave (Queen's University, Kingston, Ontario—physics); Mr. J. R. Vickery (University of Melbourne—bio-chemistry); Mr. F. P. Bowden (University of Tasmania—physics); Mr. E. R. Roux (University of the Witwatersrand—botany); Mr. R. R. Nimmo (University of New Zealand—physics).

Contemporary Birthdays.

July 16, 1872. Capt. Roald Amundsen.
July 18, 1853. Prof. H. A. Lorentz, For. Mem. R.S.
July 21, 1873. Sir Walter Morley Fletcher, K.B.E., F.R.S.
July 21, 1873. Prof. Howard T. Barnes, F.R.S.
July 22, 1865. Sir Richard Redmayne, K.C.B.
July 24, 1856. M. Charles Émile Picard, For. Mem. R.S.
July 24, 1853. M. Henri A. Deslandres, For. Mem. R.S.
July 25, 1854. Mr. Alfred Barnard Basset, F.R.S.

Prof. LORENTZ, an alumnus of the University of Leyden, was born at Arnheim. He was elected to the chair of theoretical physics in that University in 1875, and among his former pupils was Prof. Zeeman. The Nobel prize in physics was allotted to both of them in 1902. Rumford medallist of the Royal Society in 1908, Prof. Lorentz was awarded the Copley medal in 1918. While his researches as a mathematical physicist of the first order have covered many fields of investigation, his principal work has dealt with the theory of electrons and the constitution of matter considered as an electrodynamic problem.

Sir WALTER FLETCHER, who was born at Liverpool, is a graduate of Trinity College, Cambridge. He is Secretary of the Medical Research Council.

Prof. HOWARD T. BARNES was born at Woburn, Mass., and educated at Montreal Academy and McGill University. Originally a demonstrator in the chemistry department of McGill, he became in 1908 Macdonald professor of physics there, and, soon after, director of the Physics Building. For long he was ice engineer of the Hydro-Electrical Power Commission of Ontario. Prof. Barnes invented the micro-thermometer ice preventive method. He has written many memoirs concerning ice formation, specific heats, and radioactivity.

Sir RICHARD REDMAYNE, consulting mining engineer, was born at Gateshead-upon-Tyne. Following private tuition he attended Durham College of Science, and afterwards he became a mining apprentice at Hetton Collieries. Sir Richard was H.M. Chief Inspector of Mines, 1908–20. A member of many Royal Commissions on mining operations, he has been responsible in the main for the respective official reports. Sir Richard is a chevalier of the Legion of Honour.

M. PICARD, eminent as a mathematician, was born in Paris and educated there at the École Normale Supérieure. From 1879 until 1881 he held a professorial chair in the University of Toulouse. One of the permanent secretaries of the Paris Academy of Sciences, he is a commander of the Legion of Honour. M. Picard is an honorary member of the Royal Society of Edinburgh.

M. DESLANDRES, the distinguished director of the Astronomical and Physical Observatory at Meudon, was born in Paris and educated at the École Polytechnique. An active member of the International Astronomical Union, M. Deslandres is an officer of the Legion of Honour. He has many written memoirs on general and physical astronomy.

Mr. BASSET, a Londoner, graduated at Trinity College, Cambridge, as 13th wrangler. He is the author of a treatise on physical optics, and other works.

Societies and Academies.

LONDON.

Mineralogical Society, June 15.—S. I. **Tomkeieff**: On some chloritic minerals associated with the basaltic Carboniferous rocks of Derbyshire. Certain leptochlorites occurring as vesicular infillings in the Carboniferous lavas ('toadstones') of the North Derbyshire area are described. The chemical analysis of a finely spherulitic chlorite from Calton Hill places it definitely in the delessite-diabantite series. Some other chlorites from Miller's Dale are less crystalline and show a peculiar development of bacteria-like aggregates, similar to those observed in the chlorophæite of Dalmahoy Hill, near Edinburgh. All these chlorites can be compared with the chloritic palagonite occurring in the mesostasis of the non-vesicular basalt of the same lava flow, and it is suggested that both varieties of chlorite are primary, and were formed during the final stages of the solidification of the magma (autopneumatolitic).—F. L. **Stillwell**: On the nature of berthierite. A chemical analysis of berthierite from Nullamanna, near Inverell, New South Wales, gave the formula $3FeS . 4Sb_2S_3$. Microscopical examination of polished and etched sections of the material shows an intergrowth of about 18 per cent. of stibnite. Deducting this from the results of the chemical analysis, the formula of berthierite becomes $FeS . Sb_2S_3$.—L. J. **Spencer**: A sperrylite crystal from the Transvaal. Crystals of sperrylite (the rare platinum arsenide, $PtAs_2$) up to half-an inch across have recently been found in the Potgietersrust platinum fields, Transvaal. The crystal examined measures 5·0-5·5 mm. across and weighs 1·294 gm. It is a brilliant cubo-octahedron developed on all sides and with the corners and edges much rounded. The rounded areas give a profusion of scattered reflected images, few of which lie in the principal zones on the crystal. The only forms identified with certainty are (100), (111), (110), (210), (211).—H. E. **Buckley**: The anomalous optical properties of some new series of isomorphous double tartrates. In addition to the mixed crystals $\{m\ NaK,\ n\ Na(NH_4)\}\ C_4H_4O_6 . 4H_2O$, previously examined, optical anomalies of the same kind have now been determined for the series $\{m\ KNa,\ n\ K(NH_4)\}\ C_4H_4O_6\ 4H_2O$ and $\{m\ (NH_4)Na,\ n\ (NH_4)K\}\ C_4H_4O_6 . 4H_2O$ All these crystals are orthorhombic and isomorphous, but when freshly prepared they show crossed dispersion characteristic of monoclinic crystals (borax type). On standing, the crystals show a slow change in the size of the optic axial angles and in the position of the optic axial planes for different colours; and finally, after a lapse of some time, they settle down with all the optic axial planes lying in the plane (100) or (010) or in both, giving in the latter case crossed axial-plane dispersion of the orthorhombic (brookite) type. This change is hastened by rise in temperature and retarded by pressure. Sections from the outer and inner portions of the crystals showed a difference, evidently due to the time taken for growth; but in the final state they are identical, suggesting that the crystals are homogeneous. Other isomorphous series of mixed crystals containing only two of the three bases, namely $\{m\ Na_2,\ n\ Na(NH_4)\}$, $\{m\ (NH_4)_2,\ n\ (NH_4)Na\}$, $\{m\ Na_2,\ n\ NaK\}$, and $\{m\ K_2,\ n\ KNa\}$, showed, in the range of the visible spectrum, the optic axial planes all in one plane, but with wide differences in optic axial angle.—G. T. **Prior**: On the South African meteorites, Vaalbult, Witklip, and Queen's Mercy. The Vaalbult meteoric iron is a very deeply and broadly pitted mass weighing about

26 lb. which was found on a farm in the Prieska Division, Cape Province. It is a coarse octahedrite having a percentage of nickel of about ·7. The Witklip meteoric stone fell on May 26, 1918, at about 9.40 A.M., after the appearance of a luminous meteor and loud explosions, on the farm Witklip in the Carolina District, Transvaal. Fragments weighing together only about 22 gm. appear to have been preserved. It is a grey chondrite closely resembling the Cronstad meteoric stone. Of the Queen's Mercy meteorite a large stone, a foot and a half long, fell, on April 30, 1925, at Queen's Mercy, about twenty miles from Matatiele, and was broken into small pieces by the natives. A second complete smaller stone, weighing about 950 gm., which fell about fifteen miles from Matatiele, was obtained from Chief Jeremiah Moshesh and is now in the Natal Museum at Pietermaritzburg. The meteorite is a veined grey bronzite-chondrite containing about 15·5 per cent. of nickel-iron, in which the ratio of iron to nickel is about 10·5, and about 5·5 per cent. troilite, and having a ratio of magnesia to ferrous oxide in the pyroxene of about 5.

Royal Meteorological Society, June 16.—J. E. **Clark**, I. D. **Margary** and R. **Marshall**: Report on the phenological observations in the British Isles, 1925. This year illustrated strikingly how easily extreme conditions may cancel out each other if the year is taken as a whole. December 1924 and November 1925 stand out, one as the mildest for many years, the other among the coldest. May gave extremes of warmth and cold and was very wet. June drought and heat were extreme. Yet the year was exactly normal in temperature, and so too the mean date of flowering. Migrants were only a day late. The tree fruit was doubly hit. Early blooming after the warm winter exposed it to the inclemency of late April and May, while the June drought was fatal to young fruit set badly, and also to later-sown crops. Hay, early sown grain, roots including potatoes, did pretty well where weather permitted fair harvesting, but sunshine after mid-July was lacking. Normal plant progress was uneven in various districts, lines of equal unseasonableness showing some districts very early, others as much late. The spread over the British Isles of the cuckoo compared to the swallow shows that passing westward to Ireland from S.E. England its lag behind increases from two to ten days. But northwards to Berwick it loses only three days and then begins to catch up, finally reaching north Scotland a day early on the average of thirty-five years. Twelve organisations are now collaborating in Europe, extending north to Scandinavia, south to Italy, and east to Russia.—S. Morris **Bower**: Report on winter thunderstorms in the British Islands, Jan. 1 to Mar. 31, 1925. February was the stormiest month in England and Wales, while January was most disturbed in Scotland and Ireland. For England and Wales the stormiest areas were mainly on or near the south coast, the southern parts of Sussex and Surrey being heavily visited.—Edward **Kidson**: Abnormal rates of ascent of pilot balloons in the lower levels of the atmosphere at Melbourne. Observations extending from 1922 until 1925 are discussed, and tables given showing respectively (1) rapid ascending currents in the atmosphere, and (2) low rates of ascent. Rapid ascending currents and low rates of ascent most frequently occur in the months of September to February inclusive, that is, in the months when the land is warmer than the air and sea. The rapid ascending currents are encountered with the greatest relative frequency at 11.00 hr. and the least at 9.30 hr. With the low rates of ascent the greatest and least relative frequencies are at the same hours. The low rates of ascent seem to be largely the product of turbulence, the balloon being caught in the ascending portions of eddy currents.

Royal Anthropological Institute, June 22.—V. Gordon **Childe**: The first colonisation of Central Europe. The first food-producing civilisation was introduced into Belgium and northern France through the gradual spread of Danubian cultivators. These may be traced back to Moravia, and it is clear that in their migration they lost elements of culture. The origin of their civilisation must be sought farther south, immediately in 'Hungary,' though not on the Danube-Tisza plain, which in the warm, wet, early neolithic period would have been uninhabitable. On the loess terraces of Serbia and the Banat a rich civilisation has been discovered from which the Moravian might be derived by degradation. The sites are located where open ridges of loess are cut by the Danube or the Tizsa, just where people coming up the Danube would be likely to halt, and often in the vicinity of ores or on auriferous streams. The remains, notably remarkable clay statuettes, and the costume these illustrate, suggest that their makers came up the river bringing with them elements of Ægean and Egyptian civilisation. In the formation of Danubian civilisation, survivals of palæolithic elements and influences from the vase-painters of Transylvania can be detected, and its spread may ultimately have been accelerated by the pressure of nomadic steppe-folk from south Russia.

PARIS.

Academy of Sciences, June 7.—L. **Lecornu**: The problem of the grindstone.—Léon **Guillet**: The tempering of lead-antimony, lead-tin, and lead-antimony-tin alloys. Referring to the recent work of Dean, Zicheick and Nix on the tempering properties of white-metal alloys, the author directs attention to earlier work by Dubosc and by himself on the same subject.—Léon **Guillet**: The cementation of copper, nickel and their alloys by tin. The cementation was produced by heating with a bronze powder (tin 25 per cent.), and results are given for copper, nickel and some alloys. The thickness of the cementation layer varied considerably, 1 mm. being the maximum. The object of the work was to produce a surface with low friction with the minimum proportion of tin.—Victor **Grignard** was elected a non-resident member in succession to the late W. Kilian.—Michel **Petrovitch**: A remarkable property of a series of double integrals.—A. **Véronnet**: Extension of the vectorial calculus to analysis and to the absolute differential calculus.— — **Noaillon**: The determination without ambiguity of the solution of the problem of Dirichlet for functions capable of summation.—Mlle. N. **Bary** and D. **Menchoff**: The integral of Lebesgue-Stieltjes and absolutely continuous functions of absolutely continuous functions.—Henry **Bénard**: The frequency laws of detached alternating vortices behind an obstacle.—P. **Dumanois**: The possibility of realising high compressions without antidetonants. By a modification of the shape of the piston of an internal combustion engine it has proved possible to obtain the same results as were obtained by the introduction of lead tetraethyl into the petrol. The comparisons were made in a car on the road.—Th. de **Donder**: The application of relativity to atomic and molecular systems.—R. **Chambaud**: A particular class of solutions of the problem of the circular ring. Application to the theory of thick circular arches.—M. **Samsoen**: The expansion of commercial glasses. Seventeen kinds

of glass were prepared, cast into rods, and the coefficients of expansion measured with the Chevenard differential dilatometer. The complexity of the problem prevents any theoretical conclusions being safely drawn from the data obtained. It was found, however, that the additive rule of Winkelmann and Schott is not valid.—Salomon **Rosenblum**: α-rays with single charge.— — **Chevenard**: The course of the isotherms representing the resistance and thermo-electric power of the reversible ferro-nickels in the interval $-200°$ C. to $1000°$ C. The experimental results, shown in diagram form, do not clearly indicate the existence of the compound Fe_2Ni, but are not definitely opposed to the possibility of its existence. Further experiments at temperatures between $-195°$ C. and the absolute zero are required.—T. **Karantassis**: Double decompositions between the halogenides of phosphorus, tin, arsenic, antimony, lead, bismuth, silicon, titanium, zirconium and thorium. From the experiments described the conclusion is drawn that in the trivalent metalloid group the iodide of an element of low atomic weight exchanges its iodine for chlorine or bromine from the halogenide of an element of higher atomic weight.—N. **Maxim**: The action of the organo-magnesium compounds on some aromatic dialkylamides.—Em. de **Martonne**: Dryness and the index of aridity.—**Jacquet**: New radioactive springs in the Puy-de-Dôme.—L. **Eblé**: Magnetic measurements in the north-east of France.—Aug. **Chevalier**: The cinchonas of tropical Africa.—Mlle. G. **Bonne**: The constitution of the gynæceum in the Chrysobalaneæ.—X. **Chahovitch**: The energy metabolism in the course of experimental scurvy. Study of the metabolic quotient. It is suggested that the increase in the basic metabolism in experimental scurvy may be due to increased secretions of the suprarenal capsules and of the thyroid gland.—Mme. L. **Randoin** and R. **Lecoq**: The inequality of the proportion of water-soluble vitamins (B) in yeast extracts of different origin. It is generally accepted that yeasts and yeast extracts are substances exceptionally rich in the water soluble vitamins. Experiments on pigeons are described which prove that all yeast extracts have not the same biological value. An extract from beer yeast appeared to contain two factors, one securing the maintenance of the animal, the other essentially curative as regards polyneuritis. On the other hand, an extract of distillery yeast contained only the first factor and, tested biologically, was markedly inferior to the extract of beer yeast.—Claude **Fromageot**: The oxidation of pyruvic acid by ceric ions. On oxidation of pyruvic acid with ceric salts the solution containing the enol form behaved differently from that containing the keto form, the former taking up more oxygen. The enol form is more rapidly oxidised than the keto form.—Raymond **Petit**: The action of a solution of basic chlorhydrate of quinine and of urethane on the blood.—Henri **Marcelet**: Studies of the oils extracted from the head of a dolphin (*Delphinus Delphis*). Oils extracted from the maxillary glands, from the nose, and from the fat surrounding the skull were submitted to complete physical and chemical examination. Large differences were observed, showing that earlier analyses of oil described as dolphin head oil must give misleading figures.—H. **Barthelemy**: The influence of the dilution of the sperm on the duration of survival of the spermatozoids of *Rana fusca* in aqueous or saline media.—Ch. **Porcher**: The alteration of the micelles of the caseinate in the calcium caseinate—calcium phosphate complex and its consequences in the action of rennet on this complex.— — **Boulard**: A method permitting fermentations to be arrested at will, especially liquids containing sugar and alcohol, and rendering these unfermentable. The method is based on the fact that a second culture does not develop in a medium which has previously served for the cultivation of the same ferment. The method is capable of industrial applications.—E. **Lesné** and S. **Simon**: New observations on the anti-rickets factor of cod-liver oil. Vegetable oils neither prevent nor cure experimental rickets, whereas certain cod-liver oils both prevent and cure. It is shown that whilst certain oils are more or less active, others are absolutely inert, even although the latter fulfil all the requirements of the Codex. It is suggested that these results prove the necessity for a biological test of cod-liver oil.—A. **Nanta**: A myxobacterial splenomegaly.—P. E. **Pinoy**: A syn-bacterium isolated from cases of splenomegaly.

ROME.

Royal National Academy of the Lincei, May 2.—P. **Burgatti**: Elastic distortions.—U. **Cisotti**: Dynamic effects of a fluid circulating between any number of thin cylinders with parallel axes.—Ferruccio **Zambonini** and Luca **Coniglio**: The presence of marked proportions of cæsium compounds in certain products of the present-day activity of Vesuvius.—M. **Cantone**: Reply to a criticism. Bemporad's criticism of the author's communication on a new method of studying experimental results.—Achille **Russo**: Absence of agamous period and individual development in *Cryptochilum echini* Maupas.—Luigi **Fantappiè**: Non-linear analytical functionals.—Francesco **Tricomi**: Inversion formula of the order of two double integrals "with asterisk."—Vladimiro **Bernstein**: Singularity of interpolar functions satisfying certain asymptotic conditions.—E. **Cartan**: Riemann's spaces in which transport by parallelism maintains the curvature.—G. **Vranceanu**: A class of anolonomous systems.—U. **Bordoni**: The transmission of heat by radiation.—F. **Persico**: Magnetic rotatory polarisation in an alternating field. The rotatory polarisation of light in an alternating magnetic field follows the variations in the field almost exactly.—Giorgio **Piccardi**: The affinity of the neutral bromine atom for the electron.

VIENNA.

Academy of Sciences, May 20.—F. **Schuster**: On vapour pressure curves.—A. **Wegener**: Observations of the twilight arch and of the zodiacal light in Greenland.—Z. **Dische** and D. **Lazlo**: The influence of carcinoma on the glycolysis of organs, especially liver and kidney.—F. **Heritsch**: The "window" of Fischbach, a vault of Semmering rocks, limestone and quartzite under the massive gneiss.—H. **Handel-Mazzetti**: New Chinese plants (fortieth and last communication), including 12 species of Gentiana.

Official Publications Received.

Conseil Permanent International pour l'Exploration de la Mer. Rapports et Procès-verbaux des Réunions, Vol. 39: Report of the North-Western Area Committee for 1924 and 1925 (Rapport Atlantique, Secteur Nord-Ouest, 1924-1925). By Prof. Johs. Schmidt. Pp. 168. Diary of Societies.

SATURDAY, JULY 17.

SOCIETY FOR EXPERIMENTAL BIOLOGY (in Department of Natural History, University of Edinburgh), at 10 A.M.—Dr. F. A. E. Crew: The Developmental Capon and Poulard.—E. A. Spaul: The Metamorphic Principle of the Anterior Lobe of the Pituitary.—W. P. Kennedy: Diet and Reproduction in the Rat.—Prof. J. H. Priestley: The Perception and Transmission of Stimulus in the Coleoptile of the Grass Seedling.—L. A. Harvey: The Relation of Cell Inclusions to Cell Metabolism.

MONDAY, JULY 19.

SOCIETY FOR EXPERIMENTAL BIOLOGY (at the Botanical Gardens, Edinburgh), at 10 A.M.—J. Gray: The Growth of Fish.—E. Philip Smith: The Effect of Acidity on Regeneration in Coleus.—J. W. Gregor: The Influence of Environment on the Formation of definite Habitat Types.—K. B. Blackburn: Some Observations on Sex and Chromosomes in Plants.—(In Department of Natural History, University of Edinburgh), at 2.30.—A. Walton: The Survival of Fertilising Capacity of Rabbit Spermatozoa *in vitro*.—A. D. Hobson: The Formation of the Fertilisation Membrane in *Echinus esculentus*.—E. Ponder: The Kinetics of Hæmolytic and Bacteriolytic Reactions.—T. Rettie: Demonstration of a Histological Method for the Early Stages of Cell Injury.

WEDNESDAY, JULY 21.

CORRELATIVE SCIENCE SOCIETY (at Royal Botanic Society of London, Regent's Park), at 3.—Waves and Vibrations—The Spectra of Nebulæ, of Temporary, Variable and Normal Stars.

CONFERENCES.

JULY 15 TO 19.

JOURNÉES MÉDICALES DE PARIS (at Paris).

JULY 19 TO 23.

BRITISH MEDICAL ASSOCIATION (at Nottingham).

SOCIETY OF CHEMICAL INDUSTRY (Annual Meeting) and CONGRESS OF CHEMISTS.

Monday, July 19.—Institution of Chemical Engineers (Annual Corporate Meeting) (at Central Hall, Westminster), at 10 A.M.—Sir Frederic L. Nathan: Industrial Efficiency and the Elimination of Waste (Presidential Address).—At 11.30 A.M.—Exhibition of Chemical Plant (at Central Hall, Westminster).—At 2.30.—(At Mansion House).—Presentation of the Society's Messel Medal to the Earl of Balfour, and Delivery of the Messel Memorial Lecture by Lord Balfour.

Tuesday, July 20.—Society of Chemical Industry (Annual Meeting) (at Hotel Great Central), at 10 A.M.—W. J. U. Woolcock: Presidential Address.—Joint Meeting of the British Chemical Plant Manufacturers' Association, the Institute of Metals, the Institution of Chemical Engineers, and the Chemical Engineering Group for a Symposium on 'Corrosion' (at Hotel Great Central), at 10.30 A.M.—Ulick R. Evans: Fundamental Principles of Corrosion.—Dr. W. H. Hatfield: Chemically Resistant Steels for Chemical Engineering.—P. Parrish: Corrosion and Erosion.—T. G. Elliot and G. B. Willey: Chemically Resistant Steels, with special reference to Very High and Very Low Temperatures.—Joint Meeting of the Bio-Chemical Society with the London Section of the Society of Chemical Industry (at Hotel Great Central), at 11 A.M.—The Scientific and Industrial Problems presented by the Hormones—the Natural Drugs of the Body:—Dr. H. H. Dale: The Experimental Study and Use of Hormones.—Dr. H. W. Dudley: The Chemistry of the Pituitary Gland and of Insulin.—F. H. Carr: The Commercial Production of Hormones.—Dr. H. A. D. Jowett: The History of Adrenalin.—Prof. G. Barger: Recent Progress in the Chemistry of Thyroxine.—Dr. J. W. Trevan: Biological Assay of Hormones.—British Chemical Plant Manufacturers' Association (Annual Meeting) (at 166 Piccadilly), at 2.30.—British Association of Chemists (at Hotel Great Central), at 3.—Dr. Stephen Miall and others: Discussion on Chemistry House.

Wednesday, July 21.—Society of Chemical Industry (Annual Meeting) (at Hotel Great Central), at 10.30 A.M.—Addresses by Sir Josiah Stamp and Sir Max Muspratt, Bart.

Thursday, July 22.—Society of Chemical Industry (Annual Meeting) (at Hotel Great Central), at 10.30 A.M.—Joint Meeting arranged by the Chemical Engineering Group with the Institution of Petroleum Technologists, and the Institution of Chemical Engineers on Power Alcohol.—Dr. W. R. Ormandy: Sugar from Wood.—D. Ross and Dr. W. R. Ormandy: Experiences with Alcohol Motor Fuels.—Joint Meeting of the Institution of the Rubber Industry and the Oil and Colour Chemists' Association (at Hotel Great Central), at 10.30 A.M.—Discussion on The Influence of Particle Size in the Paint and Rubber Industries:—Dr. D. F. Twiss: The Importance of Particle Properties in the Rubber Industry.—G. A. Klein: The Importance of Particle Properties in the Paint Industry.—Dr. S. S. Pickles: Carbon Black.—H. Green: The Necessity for a Direct Measurement of Particle Size.—B. D. Porritt and G. Gallie: An Apparatus for the Estimation of Grit in Pigments.—E. A. Murphy: The Detection of Grit in Rubber Compounding Ingredients.—A. de Waele: The Different Types of Dispersion and some Factors Determining Same.—Dr. P. Schidrowitz: Note on the Influence of Particle Shape.—N. Heaton: The Influence and Elimination of Coarse Particles.

Friday, July 23.—Institution of Chemical Engineers and the Oil and Colour Chemists' Association (at Hotel Great Central), at 10.30 A.M.—L. J. Simon and Prof. J. W. Hinchley: Discussion on Fat Extraction by Solvents.—Fuel Section (at Hotel Great Central), at 10.30 A.M.—Dr. E. W. Smith: Summary of the Symposia at Leeds and Sheffield on Solid Smokeless Fuel.

JULY 22 TO 28.

INTERNATIONAL CONGRESS ON ALCOHOLISM (at Dorpat).

JULY 26 TO 31.

FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (at Lyons).

AUGUST 3 TO 6.

INTERNATIONAL PHYSIOLOGICAL CONGRESS (at Stockholm).

AUGUST 16 TO 23.

INTERNATIONAL BOTANICAL CONGRESS (at Cornell University).

AUGUST 23 TO 28.

The Presidents of Sections and the Titles of their Addresses are as follow: *A* (*Astronomy, Mathematics and Physics*), Prof. K. Grant, Atomic Transformation; *B* (*Chemistry*), Prof. J. Kenner, Some Aspects of the Problem of Molecular Structure; *B* 2 (*Pharmacy*), A. T. S. Sissons, The Indebtedness of Pharmacy to Organic Chemistry; *C* (*Geology and Mineralogy*), Sir Douglas Mawson, The Igneous Rocks of South Australia—a brief Survey of Present Knowledge relating thereto; *D* (*Zoology*), Prof. L. Harrison, The Composition and Origins of the Australian Fauna, with special reference to the Wegener Hypothesis; *E* (*Geography and History*), Prof. E. Scott, The Discoveries of the Western Australian Coast, with especial reference to Dampier and D'Entrecasteaux; *F* (*Ethnology and Anthropology*), Prof. F. Wood Jones, The Claims of the Australian Aboriginal; *G* (*Social and Statistical Science*), Major L. F. Giblin, Federation and Finance—an Examination of the Financial Relations of States to a Federal Commonwealth; *H* (*Engineering and Architecture*), Sir John Sulman, Town Planning; *I* (*Sanitary Science and Hygiene*), F. S. Hone; *J* (*Mental Science and Education*), P. Board, Social and Economic Values in Education; *K* (*Agriculture and Forestry*), C. E. Lane Poole, Forestry and Land Settlement; *L* (*Veterinary Science*), Prof. J. D. Stewart, The Relationship of Veterinary Science to the Prosperity of the State; *M* (*Botany*), Prof. A. J. Ewart, Past and Future Development of Botanical Science; *N* (*Physiology and Experimental Biology*), Prof. W. A. Osborne, The Study of the Reflex.

AUGUST 26.

MEDICAL WOMEN'S INTERNATIONAL ASSOCIATION (at Prague): Discussions on Tuberculosis and Pregnancy; Women Police-surgeons.

SATURDAY, JULY 24, 1926.

CONTENTS.

Truth and Tradition.

A CURIOUS change is apparent in contemporary thought. The scientific revolution, with its subversive principle of relativity and its paradoxical quantum theory, invaded the calm and secluded groves of philosophy and caused a strange disturbance. The positivity of science, at least in the form which it had assumed in the nineteenth century, seeme to disappear; accepted principles and methods suddenly became suspect; old controversies lost their meaning; new worlds were being discovered. The reception of the new mathematical relativity by philosophers was at first decidedly hostile. An attitude of incredulity was followed by amazement and dismay. When the results of the eclipse observations of May 1919 were made known, and the principle of relativity, which had been formulated fourteen years before by Einstein, was found to be actually verified and confirmed, the interest was no longer confined to academic circles; popular expositions in journals and scientific manuals flooded the book market and every one was eager to be informed. A few mathematicians and many philosophers thought the whole excitement would prove to be a nine days' wonder and hoped, somewhat impatiently, that all would be explained away and that physics would again free itself from metaphysics. The principle of relativity has not been explained away; on the contrary, in an almost incredibly rapid time, it has established itself as orthodoxy. A revolution in ideas which a few centuries ago would have occupied generations now seems to take place between night and morning and while we sleep. At the beginning of the sixteenth century it was discovered by intrepid navigators that our earth is a sphere. It was not until past the middle of that century that a daring thinker suggested that the earth moves, and it was not until a century later than that, and after bitter persecution, that the revolution of ideas which it implied was accomplished.

The extraordinary thing in the present world of ideas is not the scientific revolution, but the fact that it is accepted and that no one expects it to be upset. This does not mean that the spirit of scientific inquiry has ceased its quest and is resting satisfied with its discovery. It does mean that whatever new revolutions are in the future, there is no return to the old ideas. It is the recognition of this fact which is eloquently and forcibly expressed in the two lectures before us—The Fison Memorial Lecture at Guy's Hospital delivered by Dean Inge on March 25,[1] and

[1] Science and Ultimate Truth: Fison Memorial Lecture, 1926, delivered at Guy's Hospital Medical School, March 25, 1926. By the Very Rev. W. R. Inge. Pp. 32. (London: Longmans, Green and Co., Ltd., 1926.) Paper, 1s. net; cloth, 2s. net.

the Herbert Spencer Lecture given at Oxford by Prof. Sorley on May 19.[2]

Dr. Inge points out that there are only three periods of history when knowledge has advanced by leaps and bounds—the time of the ancient Greeks, the Renaissance, and our own age—and of these the greatest accession of positive knowledge has come in our own time. He passes the brilliant pageant in review, and very impressive it is. Yet the philosopher's interest is in the conception of value, and he asks himself, what is the relation of values as they enter as factors into ethical, religious, and æsthetic experience to scientific truth, and especially to the reality which is the ultimate goal of scientific research? The profounder consciousness of contemporary science is not content to detach or dismiss these universal aspects of human experience, the ideals of beauty, truth, and goodness, as epiphenomenal existences, imparting an apparitional glow to cold mechanical order and to which our epiphenomenal minds respond with an emotional thrill. If the real nature of things is to be found in the atom of the physicists, then, as Dr. Inge points out to us, a microbe is nearer to reality than a man. We are, however, still far from the complete philosophy which would show how the different valuations which physics, history, and religion apply to experience supplement each other. This ideal consummation is yet to be attained. The formulation of such an ideal, however, shows that we are on a higher plane of thought. The reproach which has been and still is levelled at religion, that it is ever retreating from one position to another before the victorious advance of science, and that it is now preparing to die in its last ditch, is not undeserved, nor is it entirely untrue. It is the materialism of religion which has constituted its weakness. It is the "garish promises and terrifying threats" which have failed.

Prof. Sorley also is impressed with the consciousness of its own strength which is the outcome of the triumph of the new ideas in physics and biology. The same kind of confidence which Bacon and the leaders of the scientific renaissance expressed when they represented the modern inquirer, not as the patient interpreter of the old learning, but rising on the shoulders of the past, belonging not to the infancy but to the adult stage of our race. He sees to-day a revival of the same spirit which led the young Descartes to choose a military career, not influenced by desire for glory and for worldly success, or by chivalry, but by the opportunity it offered of gaining first-hand knowledge of man and Nature. All the great periods in which there has been a notable advance in science and a revolution in ideas have witnessed a break with tradition, an emancipation from authority. We are going through such a period to-day, and no more profitable subject of self-reflection can be suggested than to take stock of our traditions, their significance, their value, and the nature of the authority they impose. Is tradition a dead hand throttling the living effort? Prof. Sorley shows us the sense in which it is a vital force necessary for the carrying on of original work. "Unless the solitary thinker emerge from his solitude and sow his seed in good soil, his ideas will not fructify." "It is seldom that a second chance comes to the innovator, as it did to Mendel when his work was rediscovered and became the inspiration of a school of biologists."

The two lectures suggest important reflections on the relation of human science to human nature and individual experience. A strange phenomenon is the apparition of man! When we view him as a form of material organisation, the outcome of a biological evolution, and then compare his activity with that of other forms in the hierarchical series, there is presented a phenomenon paradoxical and unique. The unique thing in the human attainment is the power which has come to man alone (it may be by virtue of the erect position, the visual convergence, and the co-ordination of the sense of hearing with the muscles of articulation) of superposing an artificial life on his natural life. There is nothing resembling it or approaching it in the other forms of living activity. Man by reason of his emancipation from environmental conditions has undergone and is undergoing a cultural as well as a natural evolution. The conditions of this cultural evolution are very strange—opposed to, rather than in line with, the conditions of biological evolution. The mind of the ape is moulded on the environment and responds to it as it were automatically. The mind of the man is educable. The culture which a man acquires by education does not modify his nature: it is super-added to it. Man's wisdom is not the wisdom of the bee or the ant. It is artificial. We may grow daily in grace and wisdom, transforming our natural cravings into social virtues, but we do not change the natural man. We cannot transmit our culture as a heritage to the succeeding generation. If we have the gift of expression and leave behind the works which follow us, all we leave is records which set a task for those who will enter into communion with us. Every individual must tread again painfully the path we have had to tread. The flattering notion that an Oliver Twist, born in a workhouse and brought up among thieves, can retain the gentle nature which cultured parents have bestowed on him is a romantic fiction.

It is this which constitutes the real problem of the genesis, the nature, and the authority of tradition. The new generations must start their education not where

[2] Tradition: the Herbert Spencer Lecture delivered at Oxford, May 19, 1926. By Prof. W. R. Sorley. Pp. 24. (Oxford: Clarendon Press; London: Oxford University Press, 1926.) 2s. net.

the old left off, but where the old started. Our generations overlap. It might have been otherwise. Evolution might have produced forms of activity which can retain and preserve individual attainments across a complete breach of continuity. This is the normal case in the insects, but the reverse is the rule in the vertebrates, and in the human form we meet with the formation and growth of an ideal environment, cultural and adventitious. The musician cannot bequeath his acquired skill, the painter cannot impart his acquired technique, the student his erudition. Each individual starts *de novo*, and yet he can only develop under the guidance and influence of the overlapping generation. Hence there grows up around him a tradition and an authority which appear external and seem to restrain him, but which in truth he is himself creating in the very activity of the life which bursts his bondage.

H. WILDON CARR.

Ice-Domes and the Atmosphere.

The Glacial Anticyclones: the Poles of the Atmospheric Circulation. By William Herbert Hobbs. (University of Michigan Studies, Scientific Series, Vol. 4.) Pp. xxiv+198+3 plates. (New York: The Macmillan Co., 1926.) 2.75 dollars.

IN his study of the great ice masses which form the continental glaciers of Greenland and the Antarctic, Prof. Hobbs was impressed with the dome-like shape of their ice-covered surfaces. He also noticed that the predominating wind direction along their coasts had a marked outward component as though the air were sliding off the domes. It was not difficult to find a reason why air should slide off the domes in this way, for meteorologists had long been familiar with the flow of cold air down hill-sides and valleys which occurs when the surface layers of air become abnormally cold owing to intense outward radiation. Sir Napier Shaw has given the name katabatic wind to the winds formed in this way.

Starting, then, with the idea that the air is flowing off the domes outwards in all directions, Prof. Hobbs naturally concludes that it must be replaced by air which is 'pulled down' over the central parts of the dome. But this is the sort of circulation which is described in the old text-books of meteorology as anticyclonic, so Prof. Hobbs assumes that there must be an anticyclone over every dome-shaped ice-covered land. He gives the name glacial anticyclone to such anticyclones; but he categorically states "the domed ice-surface, not the snow-covered land, is the direct cause of the anticyclone" (p. 126).

The outward flow of air, however, is not steady, but takes place in what Prof. Hobbs calls "strophs." Each stroph commences with a calm, then the air starts to move outwards, slowly at first, but acquiring velocity "to accord with the law of acceleration of gravity"; when the velocity has reached full blizzard proportions the motion is suddenly arrested because of adiabatic heating, and the stroph is at an end. Thus the whole regime of the air circulations over the Antarctic Continent and Greenland with their calms, blizzards, föhns and high winds is brought under the dominion of the glacial anticyclones.

The difficulty with all such theories is that the author never knows when to stop, so Prof. Hobbs extends his theory still further. As is well known, the Bjerknes theory of cyclones and the polar front is based on the interaction between polar air and equatorial air. But Prof. Hobbs says that the air in the north polar regions is not suited for such a purpose; in fact, Bjerknes' polar air "is quite different from that encountered by explorers within the north polar region of frozen sea"; what Bjerknes' cyclones want is a dose of air from a glacial anticyclone, so Prof. Hobbs concludes that "the cold air which rejuvenates the dying cyclones on their approach to the coast of Europe from the west, instead of having polar origin, issues from the Greenland Continent during a stroph of the anticyclone" (p. 155). Prof. Hobbs also casts longing eyes on Bjerknes' families of cyclones, but it is not clear whether he claims them entirely as the product of the anticyclone; he does say, however, "when a new stroph is inaugurated a new family of cyclones is generated" (p. 153).

Not content with bringing the cyclones of the northern and southern hemispheres under the dominion of the strophs of his glacial anticyclones, Prof. Hobbs goes still further and claims that the terrestrial climatic zones owe their existence to the glacial anticyclones, and that if there were no iced domes in Greenland and the Antarctic, the world would enjoy the uniform climate which certain geologists consider existed in previous ages. Finally, it is claimed that "these northern and southern glacial anticyclones fixed in position, function as the loci of drainage from the upper wind currents and are therefore the reversing position within the general cycle of air movement—they and not the geographic poles are the wind poles of our planet" (p. 155).

Thus, by a series of plausible steps, Prof. Hobbs has brought practically the whole of the meteorological conditions of the globe and the general circulation of the atmosphere under the dominion of two relatively small ice-domes. We have not the space to criticise this elaborate theory in detail, so a few remarks must suffice. It is now generally agreed that true anticyclones exist over the Antarctic and Greenland, but

these are due to the effect of the snow surface on radiation, and would be there whether the surface were domed or not. In the clear calm air of these anticyclones katabatic winds are often highly developed, and as their direction is practically constant, being always down slope, they produce well marked sastrugi, which can frequently be seen cutting across the sastrugi caused by the blizzards. Katabatic winds, however, need very special meteorological conditions for their existence, the chief of which is that radiation from the surface layers must exceed the radiation received. This is not the case when the sun is high or when the sky is cloudy, as it generally is before and during blizzards. It is possible that the high winds in Adelie Land described by Mawson may be katabatic winds, but until the meteorological data of this expedition are published it is impossible to be certain. We can at least say that the blizzards of the Ross Sea area are not katabatic winds.

That some air from Greenland is drawn into cyclones which pass near to the Greenland coast is clear from the familiar föhn effect which is definitely associated with passing cyclones, but that the cyclonic regime over the North Atlantic would be materially modified if Greenland were reduced to sea-level we cannot accept. The old idea of ascending currents at the equator and descending currents at the poles, in the crude way in which it was formerly stated, has now completely gone. Air cannot be 'pulled down' anywhere; the thermal structure of the atmosphere entirely prevents such motion, and this is as true in Greenland and the Antarctic as it is anywhere else. G. C. SIMPSON.

Infinite Series.

(1) *The Theory of Functions of a Real Variable and the Theory of Fourier's Series.* By Prof. E. W. Hobson. Second edition, revised throughout and enlarged. Vol. 2. Pp. x+780. (Cambridge: At the University Press, 1926.) 50s. net.

(2) *An Introduction to the Theory of Infinite Series.* By Dr. T. J. I'a. Bromwich. Second edition, revised with the assistance of Dr. T. M. MacRobert. Pp. xv+535. (London: Macmillan and Co., Ltd., 1926.) 30s. net.

(1) THE second volume of Prof. Hobson's book completes a great contribution to the literature of mathematics. The second edition is double the size of the first, and is really a new book. Less than half of the present volume is devoted to Fourier series. The rest of it contains an exhaustive account of sequences and series in general.

Of the first part of the book, Chap. vii. is worthy of special remark. In it Prof. Hobson expounds a theorem of his own which states properties common to a very wide class of representations of functions—including Fourier series as a particular case. (We regret that in this chapter and elsewhere the author has continued to use the word *summable* as meaning integrable in the sense of Lebesgue and—a still more trifling criticism—that he has not adopted the arrow notation for passage to a limit.)

It may be held that among all its branches pure mathematics appears at its best in the theory of Fourier series. There is a peculiar sharpness which has been attained in many propositions (and remains to be attained in others), and there is a peculiar cleanness in the arguments which prove these propositions. To take an example at random, let the reader refer to the ten pages of Prof. Hobson's book in which he expounds the theory of Fourier transforms developed in the last three years by Titchmarsh.

This may explain the feeling one has that if there is any part of the book better than another, it is the part dealing with Fourier series. There is a unity in this chapter (scarcely possible in the earlier, more encyclopædic part of the book) which can only have been attained by great pains in fitting the work of many writers into the author's development of the subject. One source of this unification has already been mentioned in Prof. Hobson's convergence theorem.

One wishes that the author could have woven into his general scheme some of the work published since the chapter was written, which could only be referred to, such as the solution by Hardy and Littlewood of the Cesàro summability problem and the beautiful theorems of M. Riesz on the allied series. But, after all, an account of a rapidly growing subject can only be complete—as Prof. Hobson's is—at the time of writing.

The modern theory of trigonometrical series is largely due to Englishmen—one need only mention Prof. Hobson himself, Young, Hardy, Littlewood, and lately Titchmarsh. It is particularly fitting that one of them has written this book.

(2) We welcome very heartily the reappearance of Dr. Bromwich's book, the first edition of which has been out-of-print for many years, to the great loss of the post-War generation of students. Much excellent new matter has been introduced into the second edition. The most substantial additions deal with the solutions of linear differential equations of the second order, elliptic functions, asymptotic expansions, and trigonometrical series.

To make room, the section in the first edition on summability has been omitted. We cannot help feeling that in a book on infinite series *something* should be included about summability, whatever else may have

to go. It would be ungracious to urge that a discussion of Cesàro's method is more germane to the theory of infinite series than an account of Napier's invention of logarithms or of constructions for trisecting an angle, for much that is valuable and delightful in the way of miscellaneous matter has been included. It would indeed have been impossible to give an extended treatment of summability—for that one must go to Prof. Hobson's book—but we wish that the *idea* had been explained. In twenty pages one could prove theorems which show the importance of conventional methods of summation—say, in dealing with Fourier series—and we think that such a sketch would have enhanced the value of the book.

In making this comment on the choice of matter, we had in mind the advanced student: concern for the beginner now suggests a remark. We fear that the early use of the notation $a_n \dashrightarrow b_n + l$ for $a_n - b_n \dashrightarrow l$ may leave him with free and easy notions of what a limit is. Most of the advantages of the new notation seem to be covered by the symbol $\sim$, which is less dangerous.

Prominence is given to those limit-problems which present themselves naturally and at every turn in analysis. Not only to the mathematician is the book indispensable; it is also the best possible guide to any one who encounters mathematical analysis in his work. The second edition will increase the very high reputation gained by the first. J. C. B.

The Chemistry of Drugs and Perfumes.

(1) *A Text-Book of Pharmaceutical Chemistry.* By Arthur Owen Bentley and John Edmund Driver. Pp. xi + 456. (London: Oxford University Press, 1925.) 18*s*. net.

(2) *The Chemistry of Drugs.* By Norman Evers. Pp. 247. (London: Ernest Benn, Ltd., 1926.) 32*s*. 6*d*. net.

(3) *Perfumes, Cosmetics and Soaps, with Especial Reference to Synthetics.* By William A. Poucher. Vol. 1: Being a Dictionary of Raw Materials. Second edition. Pp. ix + 304 + 21 plates. 16*s*. net. Vol. 2: Being a Treatise on Practical Perfumery. Second edition. Pp. xvi + 406 + 42 plates. 21*s*. net. (London: Chapman and Hall, Ltd., 1926.)

THE issue of elementary text-books for particular groups of chemical students is usually a proceeding to be deprecated, but there is something to be said for it in the case of students intending to qualify as pharmacists, for they need special information regarding chemicals used in medicine, and they must know something about such substances as alkaloids and glucosides and the methods by which they are estimated; subjects which are outside the scope of ordinary text-books. Messrs. Bentley and Driver's book (1) meets these and other needs of pharmaceutical students, and the authors wisely point out that it must be regarded as supplementary to a general course in elementary chemistry. For use in this way the book can be cordially recommended. The few errors noted are of minor importance, such as the representation of prulaurasin as a diglucoside on p. 4 and as a monoglucoside on p. 383. It is curious that there is no reference to the digitalis glucosides or to the alkaloid emetine, both drugs of great importance in modern medicine with which pharmacists ought to be familiar.

Any one who has used such a book as Fränkel's "Arzneimittel Synthese," or skimmed through one of those formidable 'Dispensatories' published in the United States, must be appalled at the number and variety of substances which exhibit physiological action and are potential drugs. Mr. Evers's book (2) serves the purpose of picking out the valuable drugs from this mass of material, and is at least usefully suggestive as regards the lines on which progress in chemotherapy is being made. The chapters on such familiar subjects as hypnotics, antipyretics, anæsthetics, and antiseptics are well done, being neither overloaded with unimportant materials nor neglectful of essential points.

It is interesting to find that out of 218 pages of text, synthetic drugs occupy only 66 pages, the rest being required for the discussion of natural drugs containing alkaloids, glucosides, etc. It is sometimes forgotten, especially by chemists, that medicine still depends so largely as this on drugs of natural origin. The work of compilation has been carefully done, and the only points noticed as requiring attention are of minor importance, such as the implication that chenopodium oil is produced in the West Indies and Central America, whereas it is only distilled in the United States. The statement that "though numerous derivatives of such drugs as atropine, cocaine, quinine, adrenalin, and emetine have been prepared and tested, not one of the derivatives has surpassed the natural drug in maximum effect" is true only in a Chestertonian sense, for the author himself mentions quinine derivatives which surpass the parent alkaloid in activity as anæsthetics and antiseptics. Appendix I., in which this statement occurs, is a too brief summary of current information on the relationship of chemical constitution to physiological action, a subject of great importance, which merits much more elaborate treatment than it receives.

It is typical of the difficulty of keeping books like this up-to-date that Kendall's views on the properties and constitution of thyroxine, which are given in considerable detail, have been superseded by the results of the recent admirable work of Harington. Interest in

the chemistry of drugs is steadily increasing, and Mr. Evers has performed a useful service in providing students with this survey of present knowledge on this subject.

(3) A mere chemist is interested to learn from Mr. Poucher's two volumes that so many chemicals have properties which enable them to be applied to the preparation of toilet requisites, but the reader must be more than a chemist to appreciate at its full value such information as the following. "Alloxan, or mesoxalylurea, is used in the preparation of 'blush' creams on account of the fact that it will impart to the skin a delicate pink tint, if used in a very dilute form." "If too high a percentage of alloxan is employed a purple colour is produced, which may be removed by treatment with dilute nitric acid." Clearly, the modern woman may yet be driven into taking a course in chemistry in the interests of her complexion. The author is naturally not always at this high level, and the bulk of the two volumes is occupied with more prosaic information regarding the sources, production, and uses of the immense variety of materials now used in the manufacture of perfumes, cosmetics, and soap, and the recipes beloved of the practical man are abundant. The book no doubt thoroughly deserves the popularity it has obviously secured from those for whose instruction it was written. T. A. H.

Our Bookshelf.

Handbuch der Zoologie: eine Naturgeschichte der Stämme des Tierreiches. Gegründet von Prof. Dr. Willy Kükenthal. Herausgegeben von Dr. Thilo Krumbach. (1) Dritter Band: *Tardigrada, Pentastomida, Myzostomida, Arthropoda: Allgemeines, Crustacea, Arachnoidea.* Erste Lieferung. Pp. 128. 12 gold marks. Zweite Lieferung. Pp. 129-272. 15 gold marks. (2) Fünfter Band: *Solenogastres, Mollusca, Echinodermata.* Erste Lieferung. Pp. 96. 10 gold marks. Zweite Lieferung. Pp. 97-176. 8·40 gold marks. (Berlin und Leipzig: Walter de Gruyter und Co., 1925–1926.)

(1) THE section on the Tardigrada, which was finished by the late Prof. F. Richters in 1914, has been revised by the editor. It is an altogether admirable account in 61 pages of the structure, biology (including the remarkable powers of recovery after drying), development, distribution, affinities and systematics of the order, and is illustrated by 68 excellent figures, many of which are original. The editor has appended a list of about 130 memoirs on tardigrades. The Pentastomida are described in about 60 pages by Prof. R. Heymons, and this account also is praiseworthy for the adequate and well-balanced treatment of the subject. The author would place the Pentastomida between the Annelida and the Arthropoda, and near the other short-footed arthropod-like forms such as Tardigrada and Onychophora. In the section on the Myzostomida (about 80 pp.), by Prof. von Stummer-Traunfels, we find again adequate consideration of structure, biology and life-history, together with excellent figures, for the most part from recent memoirs. The effects of the presence of Myzostoma upon the respective crinoid hosts are clearly set forth. We can thoroughly recommend these three sections to the attention of teachers of advanced zoology. The remainder of the second part is occupied by a general introduction to the morphology and phylogeny of the Arthropoda, written by Dr. Anton Handlirsch.

(2) Prof. Johannes Thiele, the author of these two parts, prefers to regard the Solenogastres as separate from the Mollusca. In the account of the order (14 pp.) more might have been given on the development, and figures to illustrate the more important stages should have been provided. The part on the Mollusca contains a brief general introduction, and accounts of the classes Loricata (Chiton, etc.), Gastropoda, Scaphopoda and Bivalvia, this last to be concluded in the third part. The best of these accounts is that of the Loricata, but here again the author does not provide figures of the developmental stages or of the excretory organs.

While we admit that it is difficult to give adequate consideration to the several systems of organs of the Prosobranchia, we cannot help feeling some disappointment in looking over the account of the sense organs and nervous system (which together receive the same space as the radula), and surely it would have been more helpful to have figures of egg capsules of known origin rather than those of unknown parentage which are given on p. 67. The classification of the Prosobranchia is well done, but some of the subdivisions, *e.g.* Heteropoda, deserve fuller treatment on account of their special interest. Certain aspects of molluscan morphology, *e.g.* torsion, have not received adequate consideration. The account of the Scaphopoda occupies less than 5 pp., and the only illustrations represent the shell, the animal removed from the shell, and three of the radular teeth; there are no figures of the internal anatomy or of the developmental stages.

The systematic part of this work is satisfactory, but the descriptions of structure and development leave much to be desired. As compared with the third volume, the present volume is far less adequate in both text and illustrations.

Volatile Solvents and Thinners used in the Paint and Varnish Industries. By Noël Heaton. (Oil and Colour Chemistry Monographs.) Pp. 158. (London: Ernest Benn, Ltd., 1925.) 15s. net.

IN less than 140 pages of text the author has attempted the task of compiling "for reference and comparison detailed information as to the nature, preparation and properties of every solvent of industrial importance in the paint and allied industries." His sixty-odd substances are broadly classified under the heading of petroleum and coal-tar hydrocarbons, hydrocarbon chlorides, terpenes, alcohols, ketones, ethers, esters, and in addition, carbon disulphide. His claim that his list of individual solvents includes every one of the type indicated is scarcely correct, especially in the United States, where the lacquer trade has made enormous strides in recent years. There is a final short chapter on the general significance of the tests for solvents, with some theoretical considerations involved in their use.

A large proportion of the material in this book can be found in many theoretical organic chemistry books, and in view of the comparatively high price of the volume it might be advisable to have restricted such matter and to have dealt more with the technical application of the solvents. Some typographical errors and a fair number of obscure or slightly inaccurate statements occur, but in spite of these and the author's disclaimer to literary style in dealing with technical data, the book is exceptionally well written. It collects together a large amount of useful information on a special type of organic substances, and it should be of great use not only to the technical man but also to the organic chemist generally. J. REILLY.

Castles. By Sir Charles Oman. Pp. xii + 232 + 100 plates. (London: Great Western Railway, Paddington, 1926.) 5*s.* net.

To the two delightful volumes, "Cathedrals" and "Abbeys," the Great Western Railway has now added a third dealing with the castles on or accessible from its system. Eighty castles in the south and south-west of England and in Wales are here described in full and illustrated by many photographic plates of great beauty and a number of equally pleasing sketches in the text. All the castles with the exception of six have been carefully inspected by the author, while his son was responsible for about half the illustrations. In addition to the description of each building and the notes on its history, Sir Charles Oman has provided an introduction in which he gives the history of the castle, royal and baronial, in England, and sketches its development as well as the development in methods of attack which took place *pari passu*—a subject on which so distinguished an authority on military history is peculiarly competent to speak. Sir Charles discusses at some length what constitutes a castle, and finally defines it as a military structure used for residential purposes which is a unit as itself. It is interesting to note that the author attributes the fact that castle building virtually ceased in the fourteenth century, not so much to the development of artillery, though that was no doubt a contributory cause, as to the realisation by that time that war in the open had come to be the only form of decisive action, and it was consequently more effective to spend money on the maintenance of men-at-arms rather than in buildings.

The Chemical Analysis of Foods: a Practical Treatise on the Examination of Foodstuffs and the Detection of Adulterants. By Dr. H. E. Cox. Pp. vii + 323. (London: J. and A. Churchill, 1925.) 18*s.* net.

THE aim of the author has been to write a text book of food analysis for the general requirements of chemists who have no special experience in the analysis of foods. On the whole he has produced a compact and readable volume which contains a large amount of useful information. In eleven chapters the subjects dealt with include carbohydrates, baking-powder, fruits, tea, coffee, cocoa, mustard, pepper, wines and other alcoholic liquors, flesh foods, milk and related products, and various oils. In an appendix the Public Health (Preservatives, etc.) Regulations of 1925 are given.

Methods are often too briefly described to be of real value to the inexperienced, and the details given are not always strictly accurate. In some cases definite alterations in standard existing procedure is indicated without comment or reference to original sources. The expert analyst is certain to be disappointed in many sections of the book, for in several instances where information is required, even on common controversial problems, little help is given. There is possibly some justification for this, as the author indicates that he is not writing for the specialist, and has endeavoured only to present the elements of the subject. The book is therefore more useful in initial training than as an aid in discussing special isolated points. In a second edition with a fair amount of revision and correction a very useful text-book should result.

Economic Geography of South America. By Prof. R. H. Whitbeck. Pp. vii + 430. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1926.) 17*s.* 6*d.* net.

THERE has long been need for a text-book on South American economic geography, since much that has been written on this subject is not free from bias and is far from trustworthy. In this volume, Prof. Whitbeck, who has the necessary qualification of personal experience of South America and a wide outlook, has largely supplied the want. The physical background is merely sketched and there is little explanation of climatic processes. These are the weak sides of the book. But the economic problems are ably handled, and the human element, which is of great significance, is kept well in the foreground. States are selected as geographical entities, but within the larger States natural regions are recognised. National boundaries, traditions, and even prejudice, play too important a part in the economic life of any State to be neglected, as must happen if natural or geographical regions are chosen as the larger units for treatment. The Falkland Islands may be of small importance, but they merit more than one casual reference, at least if the book is to be used in Great Britain. There are admirable illustrations and sketch-maps and copious bibliographies, while the text shows a pleasing absence of New World phraseology.

The Human Body. By Dr. Marie Carmichael Stopes. Pp. v + 224 + 7 plates. (London: The Gill Publishing Co., Ltd., 1926.) 6*s.* 6*d.* net.

FEW will venture to deny that some elementary knowledge of the structure and working of the human body should be included in the education of every child. To further that object, Dr. Marie Stopes offers this book to adolescents and to all who missed this knowledge when they were young. In general, it is eminently suitable for the purpose; it is simple in expression, clear and accurate in detail, and easily readable by any youth of average intelligence. There are, however, certain features of anatomy and physiology which cannot adequately be explained in print; they are best left to the tact and common sense of the parent or guardian, and their omission from this book would certainly have increased its sphere of use, to those, at least, who are passing from childhood to youth. The only other criticism we have to offer is that technical terms, such as 'omos,' 'lumbus' and 'natis,' are unnecessary even in the diagrams of a book intended for lay readers.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Secondary Hydrogen Spectrum.

THE further examination of the secondary spectrum of hydrogen has led to a number of interesting discoveries since my last publication (*Roy. Soc. Proc.* A, vol. 111, p. 714, 1926). It appears that the green and red bands have the same electron jump but correspond to different sets of vibrational transitions, those for the green bands being 0→0, 1→1, 2→2, 3→3, and 4→4, and those for the red bands 1→0, 2→1, 3→2, 4→3, 5→3, and 6→5. In addition, there are five other less well developed sets of bands with the same electron jump, two in the infra-red with vibrational transitions 2→0, 3→1, 4→2 and 3→0, 4→1 respectively, and three on the violet side of the green with the respective sets of vibrational transitions 0→1, 1→2, 2→3, 3→4 and 0→2, 1→3 and 0→3. There is an intercombination between the lines of all the above bands and indications of a further combination in the members of the PR branches, which, however, are less well developed than the Q branches. The second differences of the Q branches form a square array with a common vertical difference = 2·4 and a common horizontal difference 2·8 wave number.

The blue bands have a different electron jump from the foregoing. It appears that there are less well developed bands on the violet side of these, which are connected with them and with the red bands by means of a Rydberg formula. Thus if the first element on the violet side of each band is indicated as usual by the letter A, the frequencies of the successive lines AQ (1) are given by the formula

$$\nu = 109678\,3 \times \left\{ \frac{1}{(2-\mu_1)^2} - \frac{1}{(m-\mu_2)^2} \right\}.$$

The value of μ_1 is approximately 0·067 and μ_2 falls steadily from about 0·063 to 0·058 as m increases from 3 to 7. Evidence of the bands can be found for each of the values $m = 3, 4, 5, 6, 7$. When $m = 3$ we get one of Fulcher's red S_3 lines, the one, in fact, nearest the violet end, and when $m = 4$ we get the first line at the violet end of Dieke's blue bands. There is also evidence of the existence of a similar lot of bands connected by a Rydberg formula with the green bands. There can be little doubt, in view of the above equation, that this system constitutes the band analogue of Balmer's series.

July 11.

Imperfect Crystallisation of Common Camphor.

QUITE recently (NATURE, May 22, p. 721) A. Müller described the imperfect crystallisation of behenolic acid. The crystals of this substance proved to be built up of small crystal elements which have one direction in common and a random orientation perpendicular to this direction. This seems to be the case with many long-chain compounds.

As another example of such an imperfect crystallisation where, however, the imperfection is still greater, I should like to mention common *d*-camphor (Japan camphor). This substance, which, according to Traube, crystallises in the trigonal-trapezohedral class, was studied in the course of an investigation of the space-groups of some optically active crystals. The rotatory dispersion of camphor crystals is practically the same as the rotatory dispersion of the substance in the melted, gaseous and dissolved states (L. Longchambon, Thèse, Paris, 1923; *C.R.*, **182** (1926), 769). It was therefore supposed that the crystals might prove to possess no trigonal screw-axes, and thus owe little or none of their rotatory power to the molecular arrangement within them.

Assuming that the crystals are truly trigonal or hexagonal, their tabular form is in favour of this hypothesis. Indeed, the best developed planes in any crystal (here {0001}) are generally those which are the most closely packed with molecules. The presence of a threefold screw-axis would reduce the molecular density of the basal plane to one-third of the value which would hold in the case of a threefold rotation axis.

The crystals used were found in a bottle in which they had been produced by slow sublimation, apparently over a number of years, at room temperature. They consisted of thin hexagonal plates. The X-ray investigation showed, however, that the external form of the crystals is deceiving.

With the Bragg spectrometer never more than three reflections were observed, corresponding to the planes which occur on the crystals. From them the following spacings were deduced: $d_{0001} = 5{\cdot}80$ Å.U., $d_{10\bar{1}1} = 5{\cdot}42$ Å.U., $d_{10\bar{1}0} = 6{\cdot}06$ Å.U. (indices according to Traube). Actually, d_{0001} must be multiplied by 2 to make these spacings consistent. They give for the axial ratio 1·656 (Traube, 1·685). The hexagonal unit calculated from them contains two chemical molecules (1·95). Strange to say, a reflection from {11$\bar{2}$0} was never observed on the spectrometer. Many rotation- and oscillation-photographs were taken with different settings of the crystals (with regard to the outer form). None of these photographs showed the typical hyperbolæ of spots that would be expected. All of them showed only a relatively small number of spots, more or less distributed in a circle round the centre. Although the spots corresponding to the three planes mentioned above were generally found in positions where they would be expected, still no spot that could be definitely identified with {11$\bar{2}$0} was ever found. On the other hand, there were always spots in positions which bore no definite relations to the setting of the crystal. As a consequence it was practically impossible to deduce trustworthy conclusions from the *positions* of the spots on the plates. Clearly, what are apparently good crystals are in reality no more than conglomerations. Laue photographs seem to confirm this view. Several of them were taken in a direction perpendicular to the basal plane, but a hexagonal or trigonal distribution of spots was never obtained. There were a number of broad spots which appeared to correspond to a more correctly orientated larger part; but mostly the spots were drawn out into lines and located in circles round the centre. It should be noted that no definite indication of a larger constituent could be deduced from the rotation- and oscillation-photographs. The sharp spots must correspond to small crystals having a random orientation.

A small number of spacings were obtained from the oscillation-photographs. Attempts were made to increase this number by taking powder photographs, but a real powder could not be obtained. Rubbing camphor in a mortar effects an orientation of the crystal elements with the basal planes more or less parallel to the surface of the pressed substance. An oscillation photograph of this surface gave a strong reflection corresponding to the spacing of the basal plane. Subliming quickly on a cold surface produced crystals which were too big to be considered as a powder.

The spacings obtained are not sufficient to determine definitely the crystal unit. When a hexagonal or trigonal unit was assumed, it was only possible to account for the spacings by taking a much larger unit than would follow from the spectrometer measurements and assuming a number of accidental halvings, etc. In the course of the investigation there were also indications which seemed to point to the possibility that the crystals are not truly hexagonal but intergrowths of biaxial lamellæ. For example, on several photographs double spots were present, and once a very fine stratification of lines making angles of 60° with each other was observed on a thin layer of camphor which crystallised on the surface of a solution of camphor in aqueous methyl-alcohol. If the crystals are really biaxial, an artificial spiral of lamellæ must be present to account for the uniaxial nature of the composite crystals.

The imperfection of the crystals is probably due to the changes in temperature during the long time which is necessary for their growth. With rising temperature crystal elements resublime, whereas at lower temperatures new crystal elements are deposited. It is possible that the orientations of these latter are variable.

It is hoped that crystals will be grown from a solution later, and that better results will be obtained with them.

Influence of Temperature on Biological Processes.

THE study of Van 't Hoff's law in biology has led to the following main conclusions:

1. Biological reactions showing a $Q_{10} = 1.1$ are of a photochemical nature.
2. Biological reactions with a negative Q_{10} are based upon surface forces.
3. In the remaining cases the Q_{10} lies between 1·3 and 6·0, but usually this value depends much less on the nature of the reaction involved than on the temperature itself, the Q_{10} of one and the same reaction being higher at low than at high temperatures. Thus in these cases the Q_{10} is not a true constant, and Van 't Hoff's formula does not fully hold. It might be noted here that even in many chemical reactions the Q_{10} is not absolutely constant but that it varies slightly with the temperature. In the overwhelming majority of biological processes, however, this variation is much more considerable.

For that reason some investigators have introduced the Arrhenius formula $\left(\frac{v_2}{v_1} = e^{\frac{\mu}{2}\left(\frac{1}{T_1} - \frac{1}{T_2}\right)}\right)$ into biology. Ch Snyder[1] was the first to do so, and has been followed, in recent years, chiefly by W. J. Crozier.[2] The latter author, however, finds that the coefficient μ of the above-mentioned formula of Arrhenius is not always uniform for one and the same reaction, but that it has in many cases at least two, and according to Cole[3] even three, different values for different ranges of temperature. Thus the Arrhenius formula should not be generally used in biology (see Heilbrunn's criticism[4]).

Many biological observations unfortunately are not sufficiently accurate to serve as the basis for a quantitative law. However, after trying various mathematical formulæ for a large number of cases recorded in the literature, I have found that the following equation usually represents the relation

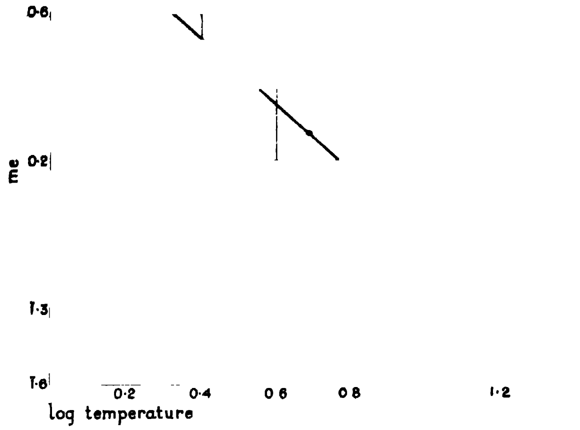

FIG. 1.—Effect of temperature on the locomotion of marine amœbæ (Pantin's experimental data).

between the temperature (x) and the time (y) necessary to accomplish a given reaction:

$$y = \frac{a}{x^b}, \qquad (1)$$

a and b being constants. In logarithmic form the formula becomes:

$$\log y = \log a - b \log x, \qquad (2)$$

which means that the logarithm of time plotted against the logarithm of temperature gives a straight line The following examples, which give good lines, show that the formula is very general.

Reaction.	Species			
Pulsation of the vacuole	Paramæcium	Cole[3]	5460·0	1·87
Amœboid movement	Marine amœbæ	Pantin	7·76	0·90
Growth	*Scirpus Kisoor*	Bose[6]	346 10[12]	9·50
Oxygen consumption	*Tenebrio molitor* chrysalids	Krogh	2819·0	2·10
Vasomotor effect on ischiadicus	Cat	Howell[8]	3802·0	2·02
Regeneration	Tubularia	Moore[9]	5012·0	1·70

Figs. 1 and 2 show the curves obtained in two of the above reactions.

The constant a expresses the time at $+1°$, as it may be calculated in putting $x = 1$. It is evident that the value of a varies according to the unit of time used. The value of b is independent of the actual velocity and of the unit of time employed, because b represents an acceleration.

If $b = 1$, the formula becomes

$$y = \frac{a}{x}, \qquad (3)$$

which is the general equation of a rectangular hyperbola. Some entomologists have put forward the hypothesis that the product of temperature and time in the embryonic development of insects is a constant for one and the same species. This hypothesis may be written mathematically in the form given above (3), and is therefore only a special case of the more general equation (1).

Krogh,[10] Warburg,[11] and others have shown that

[1] Snyder, *Arch. für Anat. und Physiol.*, 1907, p. 113.
[2] Crozier, *Journ. Gen. Physiol.*, **7**, 1924; *Proc. Nat. Acad. Sci.*, **10**, 1924.
[3] Cole, *Journ. Gen. Physiol.*, **7**, 1925.
[4] Heilbrunn, *Science*, **62**, 1925.

Pantin, *Brit. Jour. Exper. Biol.*, **1**, 1924.
Bose, *Trans. Bose Res. Inst. Calcutta*, **1**, 1918.
Cf. Robertson, "Principles of Biochemistry," 1920.
Howell, Budget and Leonard, *Journ. of Physiol.*, **16**, 1894.
Moore, *Roux's Archiv*, **29**, 1910.
Krogh, *Zeitschr. für allg. Physiol.*, **16**, 1914.
Warburg, *Bioch. Zeits.*, **100**, 1919; **103**, 1920. Yabusoe, *ibid.*, **152**, 1924.

some biological reactions are affected by the temperature in such a way that the velocities themselves plotted against temperature (*not* their logarithms) give a straight line instead of the exponential curve of Van 't Hoff. Expressed mathematically, this fact may be written (v = velocity, x = temperature):

$$v = kx, \quad . \quad . \quad . \quad . \quad (4)$$

and if we take time y instead of velocity ($y = 1/v$) and if we put $k = 1/a$, we may write:

$$y = \frac{a}{x},$$

which is the same as the equation (3). Thus the linear relation between time and temperature is true when b in the general formula (1) becomes = 1.

If we construct a curve based on any arbitrary case of the general formula (1) and then calculate the Q_{10} of that curve in the same way as is usually done

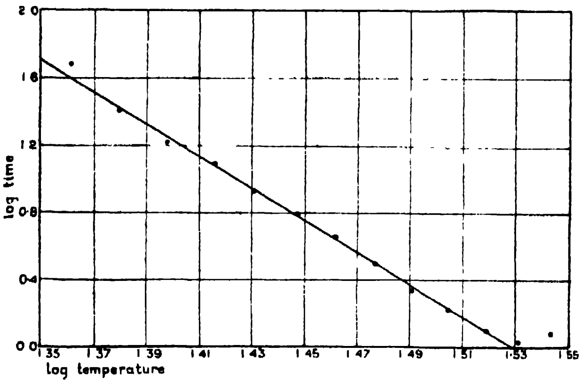

FIG. 2. Effect of temperature on growth of *Scirpus Kisoor* (Bose's experiments).

in biology, we find that the value of Q_{10} decreases with rise of temperature in the same manner as in the majority of actual biographical reactions, provided always that b is greater than 1.

At high temperatures (near and above the optimum) the formula of course does not hold, because of changes occurring in the protoplasmic equilibrium. Sometimes it may also be observed that at very low temperatures (in the neighbourhood of 0° C.) the calculated and actual values do not correspond; this is due to the fact that in the previous calculations the possible difference between the physical zero (0° C.) and the biological zero has been neglected. If the biological zero is below 0° C., the calculated points possess somewhat higher values than the points observed, and vice versa. When the temperature is measured from the biological zero (which may be expected to lie not very far from 0° C.), these divergences at low temperatures disappear.

Variations in the constant b in formula (1) appear to have considerable biological significance. I hope to show in a later note that, for the same reaction in one and the same species, b increases with age; also that it is larger in homothermic than in poikilothermic animals, and in tropical than in temperate plants.

King's College, London, June 11.

Migrations of Butterflies.

IN NATURE of April 11, 1925, p. 535, I gave an account of certain annual movements of the Painted Lady Butterfly (*Pyrameis cardui*) and ascribed them to a deliberate migratory effort on the part of the insect.

In NATURE, September 5, 1925, p. 365, and again on May 29, 1926, p. 754, Dr. E. P. Felt has suggested that this interpretation of the facts is wrong and that in reality we are dealing only with another form of the more general phenomenon of the involuntary distribution of insects by means of overpowering wind currents along the surface of the earth, or upwards by convection, and then along at high altitudes.

No one will disagree with Dr. Felt as to the frequence of involuntary distribution. On the other hand, the evidence that the seasonal movements of such butterflies as *P. cardui*, *Anosia plexippus* and various species of *Catopsilia*, etc., is an entirely different phenomenon, is too long to give in detail in a short letter. I have prepared a fuller statement of the arguments for and against, which will be published elsewhere.

However, one or two points might be summarised here.

(1) The evidence that enormous unidirectional flights of butterflies takes place at ground level, apparently independent of wind direction, or at least more often against or across the wind than with it, is overwhelming. I have more than five hundred references to flights of more than one hundred species in my bibliography for Lepidoptera alone, and the records are multiplying almost daily. The point in dispute seems to be to what distance such flights extend

(2) In the Pulney Hills in South India, Mr. Evershed has observed for more than ten years a regular stream of butterflies of four families going to the south in November and December almost every year, and a northerly stream of Pieridae in the earlier months of the year about March. He is convinced that these flights are independent of wind direction.

(3) In the Argentine, Hayward (*Entomologist*, 1925, pp. 147 and 162) records numerous butterflies 'migrating' to the north and flying near the ground when the wind was against them and high up when it was favourable, *i.e.* making use of the wind when possible but not in any way dependent on it or driven by it.

(4) Dr. Felt suggests that as the north and north-west movement of *P. cardui* between March and June over N. Africa and Europe is against the prevailing ground winds, it must therefore be due to upper air currents. I have collected information about the upper air currents in Egypt and the Mediterranean basin, and find that it is necessary to go up from two to four kilometres to get from the ground winds (prevailing north) to a permanent steady westerly upper current. At no height is there any wind current that would account for the migration. The most favourable conditions for the northerly drift of unresisting objects would be with a southerly wind. When there is such at the surface in Egypt, it has veered to south-west at a height of one kilometre and to the permanent west current between two and three kilometres. It should also be emphasised that it is not when there is a south wind, but when there is a north or north-west wind, that thousands of Painted Ladies pass steadily to the north or north-west through the Cairo district.

(5) Practically the same conditions apply with the southerly migration of the Monarch Butterfly in the eastern U.S.A. in the autumn. Neither at the surface nor at any height above it are there prevailing winds to account for the movement.

(6) If the great spread of these insects is due to involuntary drift at high altitudes, why do they continue to move, over many miles at least, in a set direction, often against the wind, when they come to the surface again? (or is it before they go up?). The mad, untiring unidirectional flight of butterflies is a thing apart from their normal flight and cannot

be accounted for except by profound physiological disturbances such as are found in birds during migration.

It is difficult not to add, although it is not argument, that if Dr. Felt had once seen a hundred thousand butterflies going headlong against the wind, or coming out of the bare desert like a thin haze, or flying out to sea without taking any other interest in a steamer than that necessary to avoid it, he would realise the complete lack of identity between this and the willy-nilly drift that carries aphids to Spitsbergen or mosquitoes and house-flies to the Rebecca Shoal Lighthouse.

Cairo, Egypt, June 10.

Series Spectra of the First Long Period.

THE regular and irregular doublet laws have been applied to some lines which appear in the high-potential spark of scandium, titanium, vanadium, and chromium, and those listed in the table appear to be the first members of the *P* doublets of Sc III to Cr VI. For convenience, those of K I and Ca II have been included from Fowler's "Series in Line Spectra."

Element	λ.	I.	ν	$\Delta\nu$.
K I .	7664·94 7699·01	10 *R* 10 *R*	13042·8 12985·1	57·7
Ca II .	3933·7 3968·5	10 *R* 10 *R*	25414·4 25191·6	222·8
Sc III .	2699·9 2734·9	10 9	37038·4 36564·4	474
Ti IV .	2067·6 2103·4	9 8	48363 47542	821
V V .	1680·4 1722·7	5 3	59510 58048	1462
Cr VI .	1446·7 1498·0	4 2	69123 66756	2367

The wave-lengths were measured *in vacuo* on a two-metre grating having 30,000 lines per inch, giving an average dispersion of 4·5 Å U. per mm.

There is no doubt that from scandium onward the intensity of these pairs falls steadily as indicated, but there is no direct comparison intended between these and potassium or calcium. It may be said, however, that calcium and scandium were taken on the same plates in some cases, and the calcium doublet was strongly reversed and apparently very much more intense than that for scandium.

When the intensity ratio of the two lines of each pair is considered, it is found that the shorter line is always the more intense of the two.

The corresponding doublet for Mn VII falls in a region having many strong lines, mostly due to silicon, and so no definite conclusion could be arrived at regarding its existence.

The origin of these pairs seems unexplained, since each of these elements from calcium onward is supposed to have but two electrons in the *N* levels, unless we assume that when these are removed some of the *M* electrons move out to take their places in a manner similar to that discussed by Catalán (*Phil. Trans.*, A, vol. 223, p. 166). Some such assumption seems necessary to explain chemical and magnetic results. It seems possible, also, that there may be some connexion between this and the decreasing intensity of the pairs.

The doublet for Sc III was arrived at independently by Mr. S. Smith, who spent considerable time looking for further series relations for this system, but while several pairs having the same separation are known, no certain results have been found.

Technical and Intellectual Values.

IN the leading article in NATURE of June 12, the Association of Teachers in Technical Institutions is invited to publish the philosophy of that branch of education in which its members are specialists. A series of principles is urgently required, and this the Association has formulated, partly philosophical, partly scientific. Control experiments to check our hypotheses are now in the process of performance through the medium of Lord Emmott's Committee of Inquiry into Technical Education, which was suggested, and the preliminary work undertaken by the A.T.T.I., but which is now under the control of an executive committee representative of industry, local education authorities, learned institutions, and technical teachers, with Mr. J. Wickham Murray as its honorary secretary. The guiding principles which are asked for will soon be in a form suitable for publication, and will then be submitted to the reading public for criticism and suggestion.

The urgent need for their formulation and publication is shown by recent speeches of the president of the Board of Education. In his opinion, secondary education is the preparation for a university education destined to provide the 'governing classes'—to use his words as reported in the press. Such a typically constricted outlook must be widened. The function of a government does not end with the manipulation of Emergency Powers Acts. Industry and commerce must be encouraged and fostered. Whether governmental philosophy be individualist or collectivist, we shall require men with technological training and capable of the application of science to the industrial world. Education must include education for service as well as for government, and this service must be intelligent: not a clumsy translation of good intentions into feeble practice.

London, W.C.1.

Natural History of the New Hebrides.

IN a few months my brother and I are going to the New Hebrides, in the Pacific Ocean, to explore the interior of the largest island, to collect the fauna, to study animal reproduction in a climate that is almost constant throughout the year, and to undertake other work of a more special nature. Particular interest attaches to a large lake on one of the islands, said to be almost the only lake in Melanesia. We are financed in part by the Trustees of the Percy Sladen Memorial Fund.

If any reader of NATURE who is a specialist in any group of terrestrial or fresh-water animals or their parasites would care to communicate with me, I should be glad to make a particular point of collecting that group and of sending the specimens to him on our return, provided that he will undertake to work out the collection and subject to the approval of the Percy Sladen Trustees.

JOHN R. BAKER.

Comparative Anatomy,
University Museum, Oxford.

The Imperfect Crystallisation of Common Things.[1]

By Sir WILLIAM BRAGG, K.B.E., F.R.S.

MANY things consist of, or contain, agglomerations of small crystals which are plain to the eye or may be made evident by the use of the microscope. Many more are only discovered to be of similar composition when they are examined with the aid of X-rays, as for example, fats, cotton and silk. In some cases the small crystals are in complete disorder. In others there is a partial arrangement; some one direction related similarly to each crystal has a tendency to orient itself more or less in a certain direction related to the body of which the crystals form part. When this happens there must necessarily be a cause for it. The body may have been subjected to strain or mechanical treatment of some sort, as when a metal sheet is hammered or rolled, or when a metal wire is drawn. Or again the body may have been formed under conditions which favour orientation, as when a substance is deposited electrolytically. Yet another case of great interest is that of animal or vegetable structure; the general orientation of the crystallites in cotton, silk, animal scales and spines, teeth and the like, has features which are clearly associated with growth.[2]

It is most probable, in some cases it is already certain, that the presence of the small crystals and their arrangement affects the properties of the body which contains them. We know that the strength of a wire depends on the arrangement of its constituent crystals; the strength of a cotton fibre, or of a bone, is most probably affected in the same way. It is part of Nature's scheme to produce this partial orientation in living things, so that a knowledge of it may be essential to the understanding of the structures which contain it. To this knowledge the X-ray diffraction figures, which are formed on the photographic plate in the customary ways, are able to contribute materially. These figures are of various types. One of them is the original Laue diagram which is obtained when a

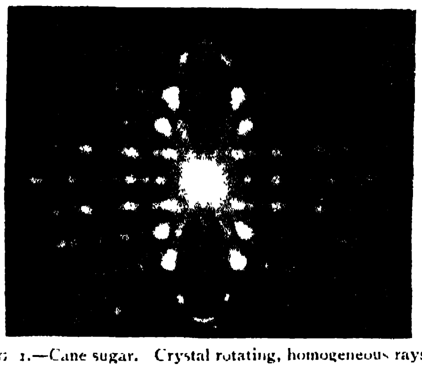

FIG. 1.—Cane sugar. Crystal rotating, homogeneous rays.

beam of heterogeneous X-rays falls on a single crystal. The lattice points in the crystal can be imagined as all lying on sets of parallel and equally spaced planes; there are an infinite number of such sets, but only a moderate number of them are sufficiently widely spaced to reflect X-rays of ordinary wave-lengths. Whenever a reflection takes place the relation $n\lambda = 2d \sin \theta$ must be satisfied, where λ is the wave-length, d the spacing of the set of planes, n is an integer,

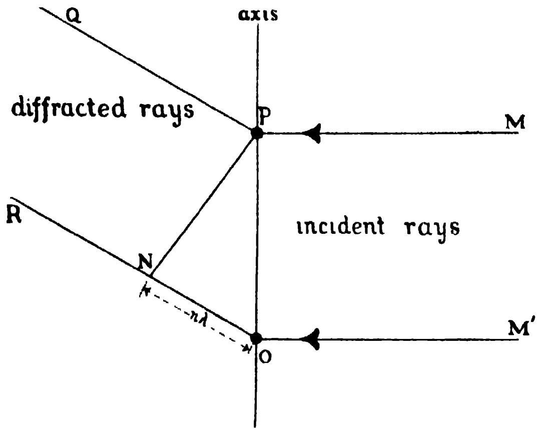

FIG. 2

and θ the angle between any plane of the set and either the incident or reflected ray. The well-known Laue photograph is formed by the reflections from the various sets of planes, each set reflecting that particular wave-length which it is able to reflect, according to the above equation. The arrangement of the spots on the photographic plate is closely connected with the symmetry of the crystal.

A second well-known type consists of a series of concentric rings; it is formed by reflections of rays of one wave-length—not mixed rays as in the previous case—which are incident on a mass of small similar crystals oriented in all directions. The explanation is that the reflection from a set of planes of given spacing must make a certain angle with the incident rays, but otherwise there is no condition which its direction must satisfy. Each ring is the aggregate of reflections from one such set. These ring photographs were introduced independently by Debye and Scherrer and by Hull, about ten years ago.

There is a third type which has been much used in recent years and is particularly important in view of the researches now under consideration. A small crystal is made to revolve about an axis perpendicular to a pencil of incident rays of one wave-length. The resulting photograph when the plate is also normal to the rays is of the character shown in Fig. 1, which is due to a sugar crystal. Each set of planes has its chance of reflecting during the revolution, provided that its spacing lies within certain limits. The spot which the reflection produces must lie on a certain circle concentric with the spot where the incident rays strike the plate; the same circle as that which was fully represented in the previous case when there was no limitation on the orientation of the crystal. But there is now a further condition; each spot must lie on one of a series of hyperbolas, such as are clearly

[1] Abstract of lectures delivered by the author at the Royal Institution on April 29 and May 6. The lectures were abbreviated on account of the industrial disarrangements of the time. It is proposed to give the lectures in full next November.

[2] The researches in this direction have been principally carried out in the Kaiser Wilhelm-Institut für Faserstoffchemie in Berlin-Dahlem by Herzog, Gonell, Mark, Weissenberg, and other workers. The photographic illustrations of this article are due to Mr. W. T. Astbury.

shown in the sugar photograph. This point is readily explained with the help of Fig. 2, which shows incident rays falling on two lattice points O and P, and diffracted rays passing away from these points. It is to be remembered that OP is extremely small in comparison with the size of the crystal, and this again is small in comparison with the distance from the crystal to the photographic plate. The incident and reflected rays are 'fine pencils,' though they contain an enormous number of such lines as MP, M'O. When there is

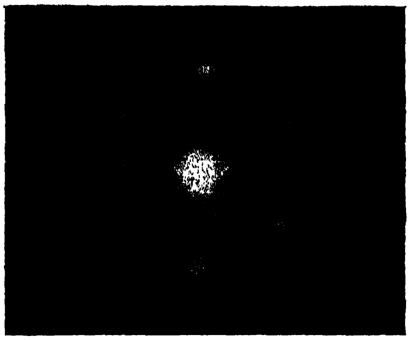

FIG. 3.—Asbestos. Bundle of fibres held steady. Homogeneous rays.

a diffracted or reflected ray from the crystal the contributions from any two such points must be in the same phase. Hence ON must be equal to $n\lambda$ where n is zero or an integer. If O and P lie on the axis of rotation, every diffracted ray must make with OP an angle $\cos^{-1} n\lambda/OP$. Thus all such rays must lie on one or other of a series of cones having OP as axis, and these cones cut the plate in a series of hyperbolas. If O and P are consecutive lattice points along OP, the first hyperbola is given by $\theta = \cos^{-1} \lambda/OP$. If θ is measured, OP can be calculated; and in this way the geometry of the lattice can be found.

A substance containing a number of small crystals having one direction in common, but otherwise oriented in a haphazard manner, gives the same photograph as a single crystal rotated about that direction during the exposure. Such a photograph is, for example, given by asbestos as shown in Fig. 3; the fibres have been set normal to the rays.

It is not often that a substance shows this arrangement in perfection, and gives a photograph like that of a single revolving crystal. Sometimes it is a spot photograph from which a number of spots are missing; it is like that of a single crystal which has not been turned through a full revolution. A bent flake of maleic acid (Müller, NATURE, May 22, p. 721) gives a photograph of this kind; if it could be bent so as to make a cylinder the tale of spots would be complete.

More often the spots are opened out into arcs of the circles on which they lie. A spot cannot move off its circle so long as the wave-length remains the same; but if there is any variability in the common direction of the crystals, the positions and spacings of the set of hyperbolæ are also variable, so that the spot broadens out along the circle on which it lies. The same effect would be obtained from a rotating photograph of a single crystal, if the axis of revolution were given some motion of its own, regular or irregular. The amount of extension of each spot into an arc varies from plane to plane, and much information can be obtained from a study of the photograph as to the possible variation in the orientation of each plane.

If there is complete uncertainty as to the orientation of the small crystals, that is to say, if there is nothing like a common direction, then a spot may lie anywhere on its circle, and we have again the ring photographs which Debye and Scherrer and Hull obtained independently.

Thus the type of photograph obtained by passing monochromatic rays through a substance shows the extent of the crystallisation. A single crystal gives no picture unless rotated. A substance containing many crystals, all having one direction in common, gives a photograph of spots, arranged in a series of hyperbolæ. The picture has symmetry about the projection of the axis on the plate; and if the incident ray is perpendicular to the axis and the plate, there is also symmetry about a line perpendicular to the projection. If there is only an approach to a common direction, the spots are drawn out into arcs of circles. If there is no approach at all, the circles are complete.

A spot never moves off its circle no matter how the crystals are oriented, so long as the rays are monochromatic. But if the rays are heterogeneous, the spot is drawn out to form part of a closed curve of a lemniscate form which crosses the circle. Photographs (Figs. 1 and 3) show traces of these curves, when the rays employed are not quite monochromatic.

The photographs of structures from several sources composed partly, sometimes almost wholly, of cellulose, all show the existence of crystals having the same lattice. Ramie (Fig. 4) gives quite a good spot photograph when the fibres are perpendicular to the rays; from which it can be concluded that one direction of the minute

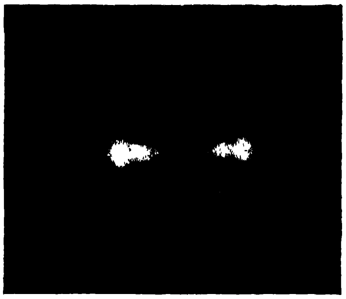

FIG. 4.—Ramie fibre. Homogeneous rays. Bundle of fibres held steady. The original photograph shows some thirty or forty spots, many of which are too faint to appear in the reproduction.

crystals is for all of them very nearly parallel to the fibre axis. It is possible, in fact, to calculate the size and form of the unit cell; the size turns out to be comparable with that of cells of ordinary organic substances. Clearly the unit of pattern does not contain the substance of many molecules, nor does each molecule contain many atoms (Herzog, *Naturwiss.*, 1924, p. 958). Cotton-wool, in the form of a small pad, gives rings, showing that its crystallites are in this case arranged entirely at random; but when a number of fibres are stretched parallel to one another there is some approach to a common axis. That the arrangement is not more complete has been ascribed to the fact that cotton fibres have a spiral structure.

It is of course no new idea that woollen, cotton and other fibres are two-phase systems at least. The elastic properties [3] point directly to such a supposition.

Mercerisation makes changes in the X-ray picture; the spots move perceptibly, but very little, and the relative intensities of some of them alter. It would appear that the general form of the lattice remains much the same, but there is some slight rearrangement of the atoms in the unit cell, perhaps an addition to them. (The cellulose photograph shows, too, that there is more than one crystalline substance present.)

Artificial silks show the structure of cellulose, as might be expected; though there are small differences in the intensities of different spots, depending on the method of manufacture. Brill has examined a number of natural silks from different sources and found the same structure in all of them.

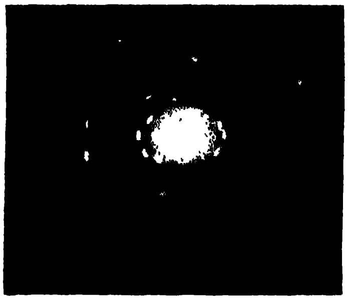

FIG. 5.—Spine of Arbacia. Laue photograph: rays heterogeneous, object held steady.

Herzog has examined chitin from various snails and insects, and found the same structure in them all. A very good spot diagram was obtained from a layer separated from the wing case of the Goliath beetle; the whole case, containing many layers, gave a blurred picture because the crystallites are not oriented the same way in the different layers.

In some cases the X-rays have confirmed previous suppositions, as, for example, that the spines of the sea-urchin consist of single crystals, or at least of aggregates of single crystals all similarly oriented in all respects, not merely in one direction (Fig. 5).

These will serve as examples of the application of the X-ray methods to various substances in the living organism. They are but a beginning, relatively few in number, and imperfectly understood.

In metallurgy the methods have been largely employed in the study of the gradual changes that take place during mechanical treatment. Rolling and drawing tend to give special orientations to the metal crystals. It has been shown by Wever, and by Owen and Preston, that in rolled aluminium foils the crystals finally arrange themselves so that (112) planes lie in the surface, a (111) direction being the direction of rolling (Fig. 6). The cube diagonals of the small cubic crystals lie in the surface; this condition is satisfied by two positions of the cubes, which are images of each other in the surface.

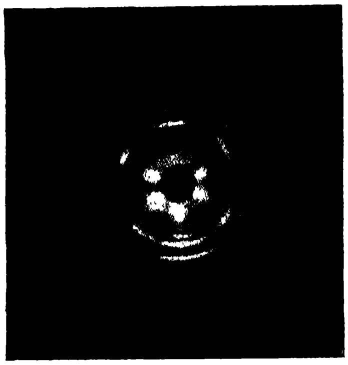

FIG. 6.—Aluminium foil rotated about an axis parallel to the direction of rolling [111]. Homogeneous rays.

The interesting point is that a certain tendency to orientation is a consequence of treatment which may be due either to mechanical handling or to some process of life. Absolutely irregular orientation cannot be generally consistent with purpose or design. Whenever small crystals exist in organic substances—and they are far more common than we have supposed—their arrangement is connected with growth, and they may be essential to it, or illustrate it, or be connected with it in some way or other which may be important to know. The X-rays show simply and conveniently the amount of any such regularity, and it is for that reason that it is interesting to apply them to a wide study of natural structures of all kinds.

The Passing of Finsbury Technical College.

THE closing of Finsbury Technical College—familiarly known as "Finsbury"—on July 26, after an existence of nearly half a century, is an event which will be generally regretted. The College was founded in 1878 by the City and Guilds of London Institute, its object being specifically to train students in the principles of science as applied to industry. In this respect it was a new departure in English education, and great interest in its future was aroused both in academic and industrial circles. The courses of instruction were in applied physics, mechanical engineering (to which civil engineering was added later), and applied chemistry, the first professors being W. E. Ayrton, J. Perry, and H. E. Armstrong. A department of applied art, under the direction of Mr. A. Brophy, was attached, and from the beginning both day and evening classes were held in all subjects. The experiment was immediately successful, and in 1885 the Central Technical College at South Kensington—also founded by the City and Guilds of London Institute—was opened. Profs. Ayrton and Armstrong were transferred to the new establishment, and were succeeded by Silvanus P. Thompson and R. Meldola, both of whom held office for more than thirty years.

Thompson on joining the staff was made principal of the College, and threw all his energy into the work. Under his direction the reputation of the College rapidly grew, and students were attracted not only from different parts of the British Isles, but also from all over the world. The day students attended for two years, and received the College certificate on passing

the prescribed examinations. Special lecture and laboratory courses were arranged for evening students, many of whom made long train journeys to take advantage of the facilities afforded. No outside examinations were held, and within wide limits each member of the staff was permitted to teach what he thought best and most useful, instead of being tied down to an examination syllabus. Under this system Finsbury flourished, and the number of students increased to such an extent that further accommodation became necessary, and a new wing was added to the College in 1904, which included a large engineering laboratory equipped with modern machinery and commodious drawing-offices. It appeared at this date that Finsbury was firmly and permanently established; but in the ensuing years various difficulties arose which threatened this seeming security, and ultimately led to the closing of the College.

The first troubles were financial. The amount available for Finsbury depended mainly upon voluntary subscriptions to the Institute from the City Companies, which were in some cases reduced in order to provide for special activities on the part of the companies concerned. The development of the College was greatly impeded by the absence of much-needed funds at a time when competitive establishments, often financed from public sources, were being organised in London and other parts of England. Temporary relief was afforded by the closing of the Art Department; but Finsbury was unable to keep so far ahead of its rivals as to attract a full complement of students from all quarters, and about 1910 a notable fall in the number of entrants, both day and evening, occurred. A contributory cause, in the case of day students, was the extension of the course to three years in order to conform with new regulations for admission to membership of the professional institutions.

At this stage the College also began to suffer from the increasing importance attached by public bodies, and even commercial companies, to the possession of a university degree, for which no provision could be made without fundamentally changing the character of the instruction. The War, with the greatly increased cost of upkeep which supervened, added further to the financial difficulties, and a great loss was sustained by the deaths of Profs. Meldola and Thompson during the War. In 1920 it was announced that the College was to be closed, and no new students were admitted in that year. As the result of a widespread agitation the London County Council offered financial aid for a period of five years, and in 1921 new students were again enrolled. The numbers joining, however, were not considered sufficient by the County Council to justify a continuation of the grant, and as the necessary sum was not forthcoming from any other source the closing of the College became inevitable.

Such, in brief, is the life-history of Finsbury; but a few words are needed to explain why it became well known all over the world. The two chief causes were an efficient and enthusiastic staff, from the principal down to the laboratory boys, and a true research atmosphere which infected the students and contributed largely to the great success they achieved in all branches of applied science. Amongst members of the staff who attained to the distinction of F.R.S. were the five early professors already named and Profs. Dalby, Coker, Morgan, and Eccles. Many important researches in applied science were carried out at Finsbury, such as the early work of Mrs. Ayrton on the electric arc; of Ayrton and Perry on electrical measuring instruments; Thompson on X-ray targets, cathode rays, and various electrical and optical devices; Meldola on dye-stuffs; Dalby on the balancing of engines; Coker and Scoble on the optical method of investigating stresses in materials and on the temperatures prevailing in the cylinders of internal-combustion engines; and Eccles on various radio devices, including the valve-controlled tuning-fork.

All these researches were fundamental, and will in themselves preserve the name of Finsbury; but a much longer list could be compiled dealing with researches in many branches of physics, engineering, and chemistry conducted by other members of the staff. It will no doubt be possible easily to distribute the students who would have attended Finsbury among other institutions, but it will not be easy to establish everywhere they may go the atmosphere of enthusiastic work and inquiry which characterised the College and brought out the best that was in the students. It has been said that the usual fate of successful reformers is to render themselves superfluous; and Finsbury, which set out to reform technical education and succeeded, has had this fate forced upon it by adverse circumstances. Whilst its demise must be deplored, it will be a satisfaction to all who have been connected with the College in any capacity that it has made for itself a lasting name in the annals of British education.

C. R. D.

The Oxford Meeting of the British Association.

OXFORD is in many respects a centre well-suited for meetings of the British Association for the Advancement of Science. It is easy of access from most parts of the country; it is well provided with accommodation for persons with moderate requirements; it is situated in a neighbourhood full of interest both historical and natural; and lastly, in its University lecture-rooms and laboratories it is able to furnish most of the conditions needed for the scientific business of the various sections.

In one particular Oxford is at a disadvantage compared with many of the places which have extended their hospitality to the Association—it is deficient in buildings large enough to collect all the members attending the meeting under one roof. It will not be possible in Oxford for even half of those who wish to do so to see and hear the Prince of Wales deliver his presidential address in his own person. The largest hall in the University—the Sheldonian Theatre—will not accommodate more than about 1500, and of these the large majority will have to submit to the discomfort of seats without backs. Conditions in the Town Hall, which has been put at the disposal of the Association by the civic authorities, are somewhat better adapted for an audience with present-day notions of comfort; though it will accommodate no larger number than the

Theatre where the address will be actually given. It is hoped that the Prince, at the conclusion of the business in the Sheldonian, will be able to visit the Town Hall, to which building his address will have been relayed. A further relay has been arranged to the debating hall of the Union Society, and in this way provision will have been secured for every one to hear the words of the president, and for nearly every one to see him.

The fact of the meeting taking place in Oxford will recall to the minds of many the records that exist of the famous meeting of 1860, which was especially signalised by the caustic reply of T. H. Huxley to the criticism passed by Samuel Wilberforce, then Bishop of Oxford, on the Darwinian theory of evolution—at that time a startling, and to the majority an unpleasant novelty. The scene of this memorable encounter was the northern section of the first-floor room in the front of the University Museum, part of which room is now occupied by the Hope Department of Entomology. To those who, like the present writer, heard the presidential address of the late Marquis of Salisbury at Oxford in 1894, there was something peculiarly impressive in the calm and measured language in which one of the former protagonists, Huxley himself, commented on an address which contained the words, "[Darwin] has, as a matter of fact, disposed of the doctrine of the immutability of species." The stage on which this latter development of the drama was played was the same as that which will witness the address of this year's president, namely, the Sheldonian Theatre. It was here, also, that the Marquis of Salisbury, on the occasion referred to, as Chancellor of the University, imparted a pleasantly light touch to the proceedings by introducing and welcoming himself as president of the British Association.

Oxford has, however, scientific associations of an earlier date. It will doubtless be remembered by many of the visitors that it was the scene in the thirteenth century of the labours and researches of Roger Bacon, the great Franciscan who, as the unflinching advocate of experimental science as against authority, was held by Humboldt to be "the most important phenomenon of the Middle Ages." [1] Perhaps some of the members of the Association will be able to find time to visit the traditional site of Roger's workshop at Folly Bridge, and the memorial tablet lately affixed to the old City Wall in close proximity to the spot where he is known to have been buried.

In Sir Archibald Geikie's happy phrase, "if Oxford was not present at the birth of the Royal Society, it at anyrate rocked the cradle of the infant." In these words he was referring to the account published in 1667 by Dr. Thomas Spratt of the meetings held "in *Dr. Wilkins* his Lodgings, in *Wadham College* (1648–59), which was then the place of Resort for Vertuous, and Learned Men." These meetings, says Spratt, in his History of the Royal Society, "laid the foundation of all this that follow'd." "By this means," he adds, "there was a race of yong Men provided, against the next Age, whose minds receiving from them [*i.e.* the men who met under Wilkins's auspices], their first Impressions of *sober* and *generous Knowledge*, were invincibly arm'd against all the inchantments of *Enthusiasm*." [2]

It need scarcely be said that the last word cited did not bear for the men of that time precisely the same meaning that belongs to it at the present day. Among the "principal and most constant of those who met at Wadham," Spratt enumerates the names of Seth Ward, the astronomer; Willis, the instructor of Lower and Mayow; Hooke, Robert Boyle, Sir William Petty, and "that miracle of a youth," as Evelyn calls him, Christopher Wren. The earliest experiments on transfusion were carried out in Oxford by Lower at the suggestion of Wren; and it is worthy of note that Sydenham, the great physician, and Mayow, the actual discoverer of oxygen and of the chemical and physiological explanation of combustion and bodily heat, were, besides Wren, all members of Wadham College, the institution presided over by the scientifically-minded brother-in-law of the Protector, spoken of by Evelyn as "that most obliging and universally-curious Dr. Wilkins."

The interest in 'natural knowledge' thus set going in the middle of the seventeenth century finds no abatement to-day; and those who will take the opportunity of the forthcoming meeting to make themselves acquainted with the scientific equipment and appliances now to be found in Oxford, will not fail to gain the impression that this ancient seat of learning is fully determined to take her proper part in the scientific progress of the present and future ages.

The Ross Institute and Hospital.

OPENING BY THE PRINCE OF WALES.

NO ceremony relating to the health and welfare of the British Empire has attracted so wide an interest as the opening of the Ross Institute and Hospital for Tropical Diseases by H.R.H. the Prince of Wales on July 15. It was the outward and visible sign of the initial success of a movement started more than three years ago to found a Ross Institute for Tropical Diseases which should include a Research Hospital. That movement had several objects in view, namely, to do honour to Ross while living for his epoch-making discovery of the method of transmission of malaria to human beings, to commemorate for all time his great achievement, to further the much-needed work of research in the prevention and treatment of tropical and sub-tropical diseases, to create a more general professional and public interest in the prevention and treatment of tropical diseases throughout the vast possessions of Great Britain in the tropics, and to assist medical men to carry out research work.

It has long been the complaint of some of the most promising men in the tropics that there was no institute in London where they could have the facilities when at home for research work on any special subject that had interested them in the tropics, which they desired to pursue further in their leisure time. The Ross Institute will now help them. France has her Pasteur

Institute in memory of her great man of science and to carry on his work. America has her Gorgas Institute at Panama, Japan has her Kitasato Institute, London has now her Ross Institute and Hospital for Tropical Diseases, the president of which is the Duchess of Portland, the chairman, Sir Charles McLeod, Bart., and the vice-chairman, Mr. Walter Shakespeare. There is a strong executive committee and council. The present medical officers are Sir Ronald Ross, director-in-chief, Dr. Castellani, director of tropical medicine and dermatology, and Sir William Simpson, director of tropical hygiene. Sir Ronald is still hale and hearty, and it must have been a source of gratification to him that, twenty-nine years after his famous discovery, and when the application of it is universally acknowledged to have resulted in the saving of an enormous number of lives and made some formerly uninhabitable places habitable, to have this Institute bearing his name opened by the Prince of Wales, who was the first to give a lead to the appeal for the necessary funds which was made in the *Times* of June 23, 1923.

The building, which contains two hospital wards, three laboratories, a library, and nurses' quarters, is not large, but it is on a healthy site facing Putney Heath, and the grounds are sufficiently extensive to allow of great additions in the future.

The Prince on his arrival at the Institute was received by the president, the Duchess of Portland, and the chairman, Sir Charles McLeod. A number of presentations were made to His Royal Highness, who afterwards inspected the wards, laboratories, and library, and then proceeded to the dais reserved for him and facing a pavilion in which more than six hundred guests were assembled. Here the chairman, Sir Charles McLeod, presented an address to the Prince in which he mentioned that His Royal Highness on his visits through different parts of the Empire and in foreign countries had landed on many tropical shores, and that his interest and sympathy cannot but have been aroused by the record of the decimating scourge of diseases incidental to these latitudes. Many of these diseases still hold the field but, thanks to Sir Ronald Ross, in honour of whose discoveries this Institute was founded, one of the greatest of them—malaria—has been or can be practically overcome. Sir Charles described the objects of the Institute, the chief of which is by research into causes of diseases to lessen the burden which weighs so heavily on labour and industry, and still more terribly on human life, in tropical and sub-tropical lands. Great strides in the knowledge of tropical diseases have been made during the last quarter of a century, and there is every hope and encouragement that in the quest and exploration of still unknown regions in medicine it will be possible to add to the stores of that science which aims only at conferring benefits on all human beings. The Prince was then presented by Sir Charles with a golden key, on which was a colour impression of the Ross Institute, and asked to declare the Institute open.

The Prince of Wales in rising to speak was received with great enthusiasm, and said :

"The opening of this Institute, which I am very glad to perform, commemorates a definite achievement in the work which the British Empire has done for civilisation. Not the least important obligation which the development of that Empire has laid on the members of our race is the constant struggle against disease in all the varied forms it can assume in different climates and in different latitudes. The struggle is always fiercest in the tropics, where man, and especially the white man, is the continual prey of diseases from which we in this country are, comparatively speaking, protected by a more temperate climate ; and perhaps the saddest page in the whole history of our Empire is that which tells of the terrible toll taken by plague and by fever of those who helped to build it.

"Of all these tropical enemies, malaria has probably been the most deadly and elusive. But now, thanks to the achievement of one man, whose name we are perpetuating in this Ross Institute, its ultimate defeat is certain. Only a few months ago I was able to see in the Sir Alfred Jones Laboratory in Sierra Leone not only the vital need for a campaign against malaria, but also the remarkable progress which has already been made in it. Perhaps I am biassed by many visits to tropical and sub-tropical parts of the world where malaria is rife, and by having talked with so many men and women whose health has been shattered by a life's work in such districts, but I can think of no other single discovery in recent times which will earn the deep gratitude of so many thousands of human beings of all nationalities as the discovery made in India by Major Ronald Ross—as he was then—on August 20, 1897. The story of its subsequent development and of what it has led to is well known to you all. I need only summarise it in the words of a famous writer : 'It is not too much to say that Sir Ronald Ross has made one-third of the world inhabitable.'

"Over a quarter of a century has elapsed since that epoch-making discovery, and this institute and hospital now stands as a memorial to the life-work of Sir Ronald and his colleagues. But it is not merely a passive memorial to work accomplished in the past ; it is also, as Sir Charles McLeod has reminded us, a very active centre for work to be done in the future. All who have any experience of the tropics will know that there is still a vast field for scientific medical research, and here, with all the resources that modern science can provide, such research can be effectively carried out, provided adequate funds are forthcoming. From this building may issue results which will bring back health to thousands who have lost it, or safeguard the lives of countless others threatened by unseen dangers in tropical lands. More than that, it may open out for the use and benefit of mankind as a whole, huge districts which are at present denied to civilisation.

"It is not surprising, therefore, that, when the scheme for founding this Institute was first put forward, it immediately received widespread public support. That support happily made its inception possible, and once the first financial obstacle was surmounted, its promoters lost no time in making it a reality. To the president, the Duchess of Portland, to Sir Charles McLeod and Mr. Shakespeare, and to Sir Ronald and his two co-directors, Sir William Simpson and Dr. Castellani, the gratitude of all of us is specially due for the time and energy they have devoted to its execution. They and their fellow-officers of the Institute may well feel proud of the result of their labours and of the knowledge that they have called into being something which cannot fail to be of incalculable benefit to many generations.

"It is with the sincere hope that further public

support for the necessary endowment may be forthcoming, and that the labours of those who will work here may be blessed with every success, that I now declare the Ross Institute and Hospital open."

After the Bishop of Southwark offered a dedicatory prayer, a vote of thanks to the Prince was proposed by the Duchess of Portland, and seconded by Sir Ronald Ross, who expressed his grateful thanks to the Prince for the kind manner in which His Royal Highness had referred to his work. He also thanked all the contributors for the honour they had done him in naming the Institute after him. The Prince replied to the vote of thanks, and after his departure the Institute was opened to the inspection of the guests.

News and Views.

ON July 14, in the House of Lords, the Duke of Northumberland directed attention to the alteration in the status of the engineer officers of the Royal Navy brought about by the Admiralty Fleet Order 3241/25 issued last November. This matter has already been referred to in these columns on several occasions. In his remarks the Duke of Northumberland said that the Order abolished the last vestige of the improved status of the engineer officer under the 1902 scheme for the amalgamation of the engineering branch with the deck officers. Not only did it relegate the engineer officer to the non-executive branch of the Navy, but it also emphasised the distinction between the deck officer and the engineer officer by re-imposing the wearing of the purple stripe. The Duke of Northumberland was supported by Viscount Chelmsford and the Earl of Selborne, the latter remarking that the point of view of the engineer officers had been recapitulated by Engineer Rear-Admiral Sheen in a letter in the *Times* of June 1, and to that he had seen no answer. Moreover, the Order might do great harm and could do no possible good. Viscount Chelmsford said that the question had arisen when he was First Lord and he had left a personal note for his successor, Mr. Bridgeman, to the effect that there had been no acute demand for the change, and that the system as it then stood was working well. The Duke of Montrose also spoke. He seemed to think that because purple had been worn by emperors, engineers should not object to it. The answer to that is, of course, that it is the way it has been imposed and what it signifies that renders it so distasteful. With his suggestions that engineer officers should have executive command of certain establishments ashore and that an engineer officer should be appointed a Sea Lord of the Admiralty a good many will agree.

THE reply for the Admiralty was made by Earl Stanhope, who repeated Mr. Bridgeman's assurance that the Order did not affect the ranks, titles, and powers of engineer officers. That, however, is not correct, for the Order does undoubtedly take away the power of engineer officers to rise to certain high appointments which they could have reached as executive officers. Earl Stanhope said that the Order was designed to sweep away an anomalous position, and divided all officers into categories according to their duties. He did not say, however, why there should be three categories of engineer officers—one for the main machinery, one for the gun machinery, and one for the electrical machinery, while navigating, gunnery, and torpedo officers all remained in one category. Such a reply will give no satisfaction in engineering circles, and does nothing towards removing that sense of injustice from which engineer officers are suffering. In view of the apparent determination of the Admiralty to stand by this Order and to impose the purple stripe, we think the Joint Committee of the Engineering Institutions, of which Sir William Ellis is chairman, would do well to issue a short plain statement of the matter as it now stands. The excellent memorandum issued some months back was too long for general distribution, and in the highest interests of Great Britain this is a matter for the widest publicity.

ON July 22 the centenary occurred of the death of Guiseppe Piazzi, the discoverer of the first of the minor planets. Piazzi was born in the north of Italy in 1746, and came under some of the most distinguished teachers of his day. He then entered the monastic order of the Theatines. A professor first at Genoa and then in Malta, in 1780 he was appointed to a chair of mathematics at Palermo. His efforts to found an observatory there were seconded by the Viceroy of Sicily, Prince Caramanico, and the observatory was opened in 1791. Piazzi meanwhile had studied Lalande's methods in Paris and Maskelyne's at Greenwich, and when he returned to Palermo in 1789 he had among his instruments a 5 ft. vertical circle by Ramsden. He devoted himself to the preparation of star catalogues, and it was while pursuing this work that in January 1, 1801, he discovered Ceres, named thus in allusion to the titular goddess of Sicily. He communicated his discovery in the first place to Oriani, who calculated the elements of its orbit, and then to Bode. Piazzi's star catalogues were published in 1803, 1807 and 1814, the latter containing 7646 stars. He served for some time as president of the Academy of Sciences of Naples, and was elected a foreign member of the Royal Society of London. By his will he bequeathed his library and instruments to the observatory at Palermo, and left an annuity for educating students in astronomical science.

THE news of the impending retirement of Prof. J. A. Fleming from the chair of electrical engineering at University College, London, a position which he has occupied since its foundation in 1885, will be received with regret by the large number of friends and students who have come under his influence. His tenure of office has been practically co-extensive with the growth of modern electrical engineering, a development in which he has taken a great part. So early as 1879 he was the scientific adviser of the original Edison Telephone Company of London, and in 1882 he was appointed to a similar position with

the Edison Electric Light Company of London, taking part in the establishment of the first electric supply stations. In 1890 he acted in the same capacity for the London Electric Supply Corporation, formed to operate the Ferranti system of high voltage electric supply, using single-phase alternating current. In '99 he was retained by Marconi's Wireless Telegraph pany to advise on the engineering work in connexion with the establishment at Poldhu of the first high power radio station in the world. Prof. Fleming has thus been in intimate touch with the early development in Great Britain of the three important electrical inventions: the telephone, the electric incandescent lamp and radio communication. During the forty-one years of his teaching work at University College, about 2000 students have passed through his department, many of whom have since achieved great distinction, there being among them three who have become presidents of the Institution of Electrical Engineers. His interest in general education has shown itself in the prominent part which he took in the work which led to the foundation of the Morley Memorial College.

PROF. FLEMING'S original contributions to knowledge are comprised in rather more than a hundred papers published in the transactions of various learned societies and covering such matters as the direct reading potentiometer, the investigation in conjunction with the late Sir James Dewar of the electric and magnetic properties of matter at low temperatures, a paper read before the Institution of Electrical Engineers in 1885 on the necessity for a National Electrical Standardising Laboratory, which gave the first impulse to the movement that resulted in the establishment of the National Physical Laboratory, and the invention of the thermionic valve, which in its modernised form is the essential element in radio communication. He is the author of a large number of very widely known text-books on electrical subjects. He was elected a fellow of the Royal Society in 1892 and received the Hughes Medal of the Society in 1910. The Royal Society of Arts awarded him its Albert Medal in 1922, especially for his invention of the thermionic valve. The Institution of Electrical Engineers has awarded him its Institution premium on two occasions, and made him an honorary member in 1923. His membership of other societies includes that of the Society of Engineers of London, the Glasgow Philosophical Society and honorary membership of the Royal Engineers' Institute, Chatham. Prof. Fleming's great gift of clear exposition and successful experimenting has created for him a special place as a public lecturer, as the audiences whose attention he has held on very many occasions at the Royal Institution have testified. He carries with him into his retirement the sincere good wishes of a large circle of friends, colleagues and students.

IN his address to the tenth annual meeting of the Association of British Chemical Manufacturers, held on July 8, Mr. D. Milne Watson, the chairman, dealt with recent activities of the Association and certain topical events, such as the coal strike, from the point of view of the chemical manufacturer. The British chemical industry may be comparatively small, yet it is advancing: during the decade 1911–21 the number of persons engaged in it increased from 0·81 to 1·15 per cent. of the total number of occupied persons in the country. Although rather jaded with fairs and exhibitions, the Association has supported the revived British Industries Fair; the view is held that chemical firms should not, as a rule, exhibit individually or indiscriminately, but unitedly as an industry at selected exhibitions. Whatever views may be held on the policy of protection, there is no doubt that the careful survey of an industry prior to legislating, such as was recently carried out in connexion with the extension of the Safeguarding Act to the fine-chemical industry for a further period of ten years, is very stimulating to the industry; on the other hand, care is needed to prevent a protected industry from becoming lethargic.

REFERENCE was also made in Mr. Watson's address to the harm done in recent years by viewing the dyestuffs industry through magnifying glasses. This industry suffers from fierce competition abroad, and from an excess of plant left over from the War. The contention that it has a secure home market is only a half-truth, for security is only given when a dyestuff is equal in quality to a competing foreign one, and when it is sold at a price which does not place the user in an unduly disadvantageous competitive position. Consolidation of interests, such as has been effected between Scottish Dyes, Ltd. and the British Dyestuffs Corporation, and between British Synthetics, Ltd. and the British Alizarine Co., is advisable and should be extended; and the lines upon which industrial development is proceeding in other countries must be studied with the view of introducing changes in the organisation of British chemical industry. The council of the Association does not see how it can take any effective or direct part in negotiating a settlement of the coal strike, but it is co-operating to that end with other industries under the ægis of the Federation of British Industries. So far, chemical manufacturers have been able to maintain stocks and to meet all demands. The fact that during the general strike only a very few employees in the chemical industry left their work is ascribed to the cordial relations which have always subsisted between masters and men, and to the circumstance that the men are for the most part really interested in their work.

IN the discussion on the chairman's address, Dr. E. F. Armstrong emphasised the need of more effective co-operation among home-producers, and also the undesirability of building up sections of the industry "which are strong because they are members of international groups, in which the British voice varies in loudness." All indications point to foreign competition becoming more fierce. The Right Hon. J. W. Wilson referred to the magnitude of the German Interessengemeinschaft and to the even greater combination in the iron and steel industry; although

the United States will probably follow suit, this line of development is not in accordance with the British temperament. Dr. G. C. Clayton, M.P., has noted the increased attention paid by the House of Commons to chemical matters, while the Government is showing considerable interest in the Department of Scientific and Industrial Research. He regards recent results obtained in the Fuel Department as hopeful, and thinks that before long an economic process for recovering the valuable products from coal and for producing smokeless fuel will see the light of day. The Germans claim that they have overcome most of the difficulties in producing liquid fuel direct from coal; we in Great Britain are not very far behind them, if, indeed, we are not actually in front.

THE annual meeting of the Society of Chemical Industry and Congress of Chemists, in which a number of societies with related interests are co-operating, opened on Monday, July 19, and in the afternoon the Messel Memorial Medal was presented to Lord Balfour by the Duke of York. After the presentation, Lord Balfour delivered the Messel Memorial Lecture, taking as his subject the relation of the State to science and industry. In tracing the association between science and industry, Lord Balfour referred first of all to the men of genius, moved solely by the desire to add to the store of human knowledge, to whom falls the glory of making fundamental discoveries. This work can be stimulated only by education. The next stage is accomplished by men of constructive ability who can see how the achievements of the scientific worker are to be applied. Then comes the time for testing the results on a scale larger than that of the laboratory experiment, and finally there is the full scale trial which, if satisfactory, means that another piece of laboratory work has been applied to the purposes of industry, and the organisation of production and marketing can proceed. A Government department can do little to further fundamental discovery and should not interfere with the last stages of development, namely, production and marketing. Its assistance should be given, Lord Balfour stated, in the middle region, where industry as a whole rather than one special branch is concerned. There has been no falling-off in the achievements of British men of science or in the business capacity of the leaders of industry, but more co-operation is needed between them, coupled with the broad and imaginative outlook which has been the basis of the great industries in other countries of the world.

IN the course of an address delivered by Sir Robert Hadfield on the occasion of the opening of new metallurgical and engineering research laboratories during the twenty-first anniversary celebrations of the University of Sheffield, the speaker reviewed the history of the University and its predecessors, the Firth College and the Technical School, and of the efforts made to establish educational facilities in connexion with the industries of the city. Although Sheffield had been for many centuries an important centre for the manufacture of steel by the old methods, it was not until the invention of crucible steel by Huntsman in 1740 that it began to assume the leading position which it has occupied ever since. It is remarkable how, the manufacture of steels of specially high quality having once been established, the existence of a skilled body of workers, and of manufacturers accustomed to the trade, favoured the introduction of new processes, so that a large number of important inventions, especially concerning alloy steels, have originated in that city. It is also appropriate that the study of metallography, which may be said to have furnished the scientific basis for all modern metallurgy, should owe its origin to a Sheffield scientific man, H. C. Sorby, a pioneer in so many branches of science. The new laboratories are equipped for the investigation of metals, and particularly of steel, by modern physical methods, in view of the remarkable results which have been attained by the application of exact physical measurement and by the study of physical properties in the improvement of metallurgical operations.

SIR ROBERT HADFIELD's address contains statistics concerning the work of Sheffield firms during the War, when the great armament plants were largely increased and enormous quantities of munitions were produced. Statistics as to present employment show the number of employed persons to be about 184,000, of whom, roughly, 42,000 are engaged in the iron and steel industry and 21,000 in cutlery, to name the two occupations most usually associated with the city. The importance of education and training for these industries is therefore obvious, and the University has set itself to meet the needs of the local population, whilst at the same time becoming a centre of post-graduate study and research. In view of the situation on the South Yorkshire coalfield, the study of coal also assumes great importance, and the Fuel Department of the University has been specially equipped for research on the utilisation of coal. One of the urgent needs of the industry is the greater application of electrical power, and interesting facts bearing on this subject are quoted by the author. Even with the existing comparatively high cost of electric power, its use in the steel industry has assumed vast dimensions.

THE fifth Hurter and Driffield Memorial Lecture was delivered by Prof. Charles Fabry before the Royal Photographic Society on April 20 last, and is published, with illustrations, in the July issue of the Society's journal. Prof. Fabry took as his subject "The Photographic Plate as an Instrument for the Measurement of Visible and Invisible Radiations," and passed in review probably all the useful methods of photographic photometry, indicating their respective advantages, difficulties, and limitations. The use of polarisers for varying the intensity of the incident beam is excellent when the light is not partially polarised, but the layer of Canada balsam present in most polarisers is absolutely opaque to ultra-violet radiations of wave-length less than 3400 Å.U. Beyond this the balsam may be replaced by air, but this gives a small angular field. Prof. Fabry adds, "I have, however, used Glan prisms with success." When

working in the ultra-violet region in conjunction with M. Buisson, it was found that the stripped gelatine film (glass being inadmissible because of its absorption) of a developed plate gave a sudden diminution of its absorptive power, transmitting about twelve times as much light at 3150 Å.U. as at a little distance on either side of this point, due to the transparency of metallic silver for radiations of about this wave-length. This difficulty was overcome by intensifying the plate with mercuric chloride and ammonia before stripping. Schumann plates are not suitable for photometric purposes because of the irregularities following from the difficulties of their manufacture, but the 'oiled plate' introduced by Duclaux et Jeantet is spoken of as perfectly suitable. A thin layer of mineral oil put upon the plate fluoresces in the ultra-violet and the fluorescent light affects the plate. An illustration shows the effect with and without the oil for wave-lengths from about 2816 to 1854 Å.U. Prof. Fabry urges the desirability of founding one's photometry on the energy (or heating power) of radiations, as this is " the only real measure of the intensity of a radiation." " Two rays which appear equal with a certain exposure may seem to be absolutely different if a longer exposure is given "

A SERIES of postcards depicting objects of scientific interest preserved in or connected with the Old Ashmolean Museum has recently been issued by the Oxford University Press. The collection comprises a set of designs representing the Old Ashmolean at different dates, including a reproduction in colour of a print by Rowlandson (1809). Another set, devoted to the Dodo, begins with an excellent coloured copy by Mrs. Gunther of the well-known picture in the Sloane Collection, and is continued by De Bry's representation of the landing at Mauritius in 1598, by the drawings of Clusius and Savery, and by photographs of the head still preserved at Oxford. An interesting series of portraits starts with Richard of Wallingford, Merton College (1292–1336), the first describer in detail of the making of scientific instruments, and ends with John Evelyn, Balliol College (1620–1706). Other notable portraits are those of Robert Recorde, All Soul's College (1510–1548), the inventor of the mathematical signs of multiplication and equality, Robert Boyle, Elias Ashmole, Christopher Wren, and John Wilkins, the last two of Wadham College. In a set representing the history of medicine occurs a drawing by Christopher Wren of the base of the brain, which for exactness of detail could scarcely be bettered at the present day.

SINCE the quantum theory of spectrum emission was started on its career by Bohr in 1913, the stream of contributions by workers in all parts of the world has been almost unparalleled in its volume and variety of character. The, as yet, semi-empirical character of the whole conception gives the widest possible scope to speculation and the formation of arbitrary practical rules, and such rules have for some time been put forward at too rapid a rate for the controlling factor of experiment to separate the false from the true. The subject has consequently become so intricate and so charged with ideas, many of which are incompatible with one another, that the experimenter who has wished to obtain a clear idea of what is being proposed has had no time left for his experiments. In particular, the notations and numerical values assigned to the various 'quantum numbers' now recognised are almost as numerous as the writers on the subject, and the resulting confusion, which is largely unnecessary, has been a serious hindrance to the acquiring of definite ascertained knowledge. The appearance of a new *Bulletin* of the National Research Council of the National Academy of Sciences, Washington, on " Quantum Principles and Line Spectra," by J. H. Van Vleck, assistant professor of physics in the University of Minnesota (Washington, D.C., National Academy of Sciences, 1926, 3 dollars), in which the many-sided activities of theoretical workers are ably summarised and compared with one another, is therefore an event of great importance. Duplication of Sommerfeld's " Atombau und Spektrallinien " has been avoided so far as possible, and particular prominence is given to the methods of approaching the subject which are suggested by Bohr's correspondence principle. The volume has been brought up-to-date during passage through the press by the insertion of numerous footnotes, and may really be said to be invaluable to the large body of workers in spectroscopy. The author is to be commended on the clearness of his exposition. Each sentence has usually only one possible meaning—a characteristic which is far too rare in many of the original papers on the subject.

ROTHAMSTED Experiment Station appears to have made a new departure in the issue, in very attractive form and under the general title of " Rothamsted Conferences, I.," of an account of a recent discussion at Rothamsted upon the growing of lucerne. This little memoir is extremely effective. The case for a further cultivation of lucerne in Great Britain is first presented by Sir John Russell and members of his staff. Experience with lucerne is then given by members of staff from various experiment stations, by private growers, by big seedsmen, etc. Lord Bledisloe, Parliamentary Secretary to the Ministry of Agriculture and Fisheries, and Lord Clinton, chairman of the Lawes Agricultural Trust Committee, contribute, as also Mr. Dampier Whetham of the Royal Agricultural Society Research Committee. This committee has helped financially Mr. H. G. Thornton's experiments upon inoculation by *Bacillus radicicola*. A summary of points collected at the conference follows upon the discussion and makes a very clear presentation of the main case for lucerne growing. It appears that lucerne has often been a failure because British soils are not infested with the strain of the nodule nitrogen-fixing organisms necessary for its healthy growth. Mr. Thornton's field trials suggest that the difficulties in the way of successful inoculation often met with in the past are now overcome and lucerne then deserves a more extended trial. It will not grow on ill-drained or shallow soil, and probably requires a fair supply of lime; it must be sown on clear land and the weeds

kept down by suitable cultivation. Given these conditions, it is apparently one of the most valuable of arable crops, and adds to the fertility of the soil, permitting a more intense farming. It gives each year after the first year usually two good hay cuts and a green aftermath for cutting or grazing.

THE Council of the Royal Meteorological Society has awarded the Howard Prize for 1926 to Cadet B. W. Harman, of H.M.S. *Worcester*, for the best essay on "The Causes and Distribution of Fog in the North Atlantic."

DR. W. H. GIBSON has been appointed Director of Research for the Linen Industry Research Association in succession to Dr. J. Vargas Eyre. Dr. Gibson was educated at University College, London, under Sir William Ramsay, and afterwards spent twelve years at the Research Department, Royal Arsenal, Woolwich; for his services in connexion with high explosives research during the War he was awarded the M.B.E. in 1918 and the O.B.E. in 1920. For the last seven years he has been in charge of the Research Department of a prominent linen firm in Belfast.

EXCAVATIONS on prehistoric sites in the Crimea are about to be commenced under the auspices of the Russian State Academy for the History of Material Culture by G. A. Boutch-Osonolovsky. The first site to be attacked is the Kik-Koba cave, where it is hoped may be discovered missing parts of an early human skeleton already found. Exploration will then be extended to the hill caves of later palæolithic age in continuation of the investigations which were begun in 1924.

IT is stated in *Science* that, at the annual meeting of the Geological Society held at Peking on May 3-5, the first presentation was made of the Grabau Medal, founded by Mr. C. Y. Wang for "accomplishment in the field of geological research in China, or for original advancement of the science throughout the world." This first award was made to Prof. Amadeus W. Grabau, who has been largely responsible for the training of an active group of young Chinese geologists and has himself contributed to our knowledge of the invertebrate fossils and palæogeography of China and Central Asia.

THE secretary of the Department of Scientific and Industrial Research announces that a licence, under Section 20 of the Companies (Consolidation) Act 1908, has been issued by the Board of Trade to the British Food Manufacturers' Research Association, which has been approved by the Department as complying with the conditions laid down in the Government scheme for the encouragement of industrial research. The secretary of this Association is Mr. R. M. Leonard, 22 Buckingham Gate, London, S.W.1. The investigations of the Association will be conducted in close co-operation with those of the British Association of Research for the Cocoa, Chocolate, Sugar, Confectionery, and Jam trades.

PROF. H. H. BARTLETT, Director of the Botanical Gardens of the University of Michigan, who has just been appointed honorary collaborator of the Smithsonian Institution, is about to make collections of the flora of Sumatra and Formosa for the Smithsonian Institution and the University of Michigan. The flora of Sumatra, which is exceptionally rich from the scientific point of view as well as economically important, is poorly represented in the United States collections. During a year previously spent in studying the rubber-producing plants of Sumatra, Prof. Bartlett's attention was attracted to the folklore of the poorer Malays, and especially to their custom of writing beliefs, legends, and descriptions of the magical and medicinal properties of plants on the internodes of green bamboos which are afterwards dried and preserved. This folklore has received little attention hitherto. Prof. Bartlett proposes to devote some part of his time to the study of it as well as the language during his stay in the island.

REFERRING to the review entitled "Eugenic Reform" in NATURE of July 10, p. 39, Mrs. C. B. S. Hodson writes stating that her share in Major Leonard Darwin's book "The Need for Eugenic Reform" was confined merely to proof-reading for the detection of printer's errors.

UNDER the title "Instructions to Collectors: No. 7—Blood-sucking Flies, Ticks, etc." (1926: price 6*d*.), the British Museum (Natural History) has issued a fifth edition, revised and enlarged, of a useful illustrated pamphlet. The Museum requires carefully collected and properly labelled material of this kind from practically all parts of the world. Medical men and others who may be willing to help in the collection of specimens will find within its pages full directions for the collecting, mounting, and transmission to England of such material (other than mosquitoes).

MR. E. PICKWORTH FARROW'S book upon the plant life of East Anglian Heaths was recently reviewed in these columns (NATURE, December 19, 1925, p. 896). Based upon the experience of vegetation study recorded in this book, Mr. Farrow communicated a brief article entitled "The Study of Vegetation" to *Discovery*, which is intended to stimulate and, to some extent, to guide the beginner in this fascinating field of inquiry. In an enlarged form this article has now been reprinted as a pamphlet which is published by Messrs. Blackie and Son, Ltd., on behalf of the Coastal Research Laboratory and Bird Sanctuary at Blakeney Point, Norfolk (price 2*s*.). The price of the pamphlet may seem a little high, but all proceeds from its sale go towards the maintenance of this well-known centre of ecological research, now under the National Trust.

THE Fuel Research Board of the Department of Scientific and Industrial Research has just issued a further pamphlet in the series of the Physical and Chemical Survey of the National Coal Resources. This pamphlet, No. 6, is the fourth dealing in detail with one of the seams of the Lancashire Coalfield, the present one being devoted to the King Seam; sections of the coal in various parts of the coalfield are given as it happens to vary a good deal both in thickness and in quality, the latter point being brought out by analyses of the coal from a number of points in the

coalfield. This pamphlet is on precisely similar lines to those previously published, and gives a mass of valuable information concerning the coal seam under discussion.

MESSRS. J. J. Griffin and Sons and Baird and Tatlock have issued a joint catalogue, No. 50, of scientific apparatus mainly for physics. It is well printed and bound and has 735 pages, 14 of which are devoted to the index. In the section on light, an X-ray spectrograph, neon lamps, and a number of new optical benches are described. Under electricity, several new forms of galvanometers, resistance boxes, selenium cells, and electric furnaces are to be found.

THE latest catalogue (New Series, No. 19) of Messrs. Wheldon and Wesley, Ltd., 2 Arthur Street, W.C.2, deals with upwards of 3000 works relating to astronomy, classified as follows: History, biography, bibliography; origin and development of astronomy from Aristarchus to Sir W. Herschel; periodicals, publications of societies and observatories; elementary works, treatises, dictionaries; spherical and theoretical astronomy; celestial mechanics; practical astronomy; spectroscopy, solar and stellar spectra, photometry, photography; astrophysics, cosmogony; the sun, transits, sunspots; eclipses; Mercury, Venus, minor planets; the earth; the moon; Mars; Jupiter; Saturn, Uranus, Neptune; comets and meteors; stellar astronomy; double and multiple stars; variable stars, red stars and nebulæ, clusters, Milky Way.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—Demonstrators in civil and mechanical engineering in the University of Leeds—The Registrar (July 28). An assistant lecturer in philosophy at the University College of Wales, Aberystwyth—The Secretary (August 3). An assistant in the department of physics of University College, London—The Secretary, University College, Gower Street, W.C.1 (August 7). A lecturer in biology and chemistry at the Municipal Technical College, Swansea—The Director of Education, Education Office, Dynevor Place, Swansea (August 9).. A chemical pathologist and lecturer on chemical pathology (jointly) at St. Bartholomew's Hospital Medical College—The Dean of the College, E.C.1 (August 16). A professor of music at the University College of Wales, Aberystwyth—The Secretary (August 25). A lecturer in moral philosophy in the Queen's University, Belfast—The Secretary (August 31). An assistant master at the Kingston-upon-Thames Technical Institute, to teach engineering workshop practice—The Principal.

Our Astronomical Column.

KOPFF'S PERIODIC COMET.—This short-period comet was discovered by Kopff in 1906, and was detected again after two revolutions in 1919. It passed perihelion last January, when ephemerides were published in the *B.A.A. Handbook* and elsewhere. However, the comet was then badly placed for observation, being nearly behind the sun; it escaped observation for six months after perihelion. Prof. M. Wolf succeeded in photographing it on July 13 at $1^h\ 5{\cdot}2^m$ U.T. in R.A. $1^h\ 17^m\ 12^s$, N. Decl. $18°\ 14'$, the magnitude being 16. The observation indicates Jan. 27·15 as the date of perihelion. The other elements are taken from the *Handbook*:

ω	19°	43′	29″	log q	0·232113
Ω	263	55	10	e	0·51422
i	8	41	30	Period	6·5842y

The comet is probably only observable with large reflectors; the following ephemeris is for 0^h U.T.:

	R.A.	N. Decl.	log r.	log Δ.
July 26.	$1^h\ 27^m\ 48^s$	19° 55′	0·3680	0·3060
Aug. 3.	1 32 24	20 47	0·3761	0·2949
11.	1 35 33	21 31	0·3839	0·2828
19.	1 36 48	3	0·3917	0·2715

THE CONSTITUTION OF THE INTERIOR OF THE EARTH.—Dr. H. Jeffreys read a paper on this subject at the June meeting of the Royal Astronomical Society which is printed in vol. 1, No. 7, of the Geophysical Supplement of the *Monthly Notices, R.A.S.* It has hitherto been supposed that the rigidity near the earth's centre is very great, but since it was discovered that secondary seismic waves are (apparently) not transmitted through this region, Dr. Jeffreys reinvestigated the data for rigidity in the interior, including that based on the tides, and finds that they are quite consistent with the interior being composed of liquid iron, possibly with an admixture of nickel. The depth of the outer boundary of this liquid core is given as 2900 km. or 0·455 of the radius, this being the surface of discontinuity of seismic waves found by Gutenberg. Though mainly geophysical, the paper has also an astronomical bearing.

LARGE SOLAR PROMINENCE.—The recent appearance of a very large prominence has been reported by Mr. Newbegin observing with his solar spectroscope at Sutton. On July 16 at $10^h\ 25^m$, it extended 40° around the sun's west limb—from position angle 276° to 316°—and its height was then 85 seconds of arc. Probably it is the largest prominence observed as yet during the present cycle. Its character was of 'massive' formation and quiescent in type. An amount of fine detail is indicated by Mr. Newbegin's sketch, the prominence appearing to be composed of a number of tree-like structures rising at more or less equal distances from the chromosphere and connected together by branching filaments.

As a class, the large massive prominences last for some time—frequently for several weeks—and although usually found within the sunspot zones they are rarely, if ever, seen above a spot. In the present instance there was no spot in the vicinity, but there were faint patches of faculæ which were the remains of the extensive area connected with the great spot of December and January last. Indeed, the position of the prominence, at least for a portion of it, is almost identical with that of this spot. The mean position of the spot during its two transits in December and January was longitude 32°, latitude 22° N. Allowing for the average polar retardation at latitude 22°, the longitude of the place originally occupied by the spot was 0° on July 16, while the longitude of the sun's western limb on the same day at the time of Mr. Newbegin's observation was 2°.

Spectroheliograms showing disc markings and limb phenomena have doubtless been secured at several observatories equipped with spectroheliographs and should give additional information of great value as to the life-history of this large prominence, which is evidence of a recrudescence of activity in the chromosphere above an extinct sunspot. It may be added that no unusual magnetic disturbance has recently been recorded in this connexion.

Research Items.

EFFECTS OF MENTAL WORK.—A paper of great interest on the changes which take place in the metabolism of the body during severe mental work has been published by Prof. V. Suk of the Masaryk University, Brno, Czechoslovakia (*Bull. internat. de l'Acad. des Sc. de Bohême*, Nov. 20, 1925). Prof. Suk took the following three groups of students: Group 1—29 men undergoing physical training in a teachers' college; group 2—31 members of the highest class in a *gymnasium* working for final examinations; group 3—31 members of another class also working for examinations. He kept these three groups under observation for three months, keeping a record of the amount of hæmoglobin and of sugar in their blood. There was a slight increase on the percentage of hæmoglobin in those undergoing physical training while that in the brain-workers remained stationary. On the other hand, while the blood-sugar remained stationary in those who exercised their bodies, there was a fall of 36-38 per cent. in the sugar content of the blood in the brain-workers. Severe and prolonged mental toil, therefore, does interfere with the carbohydrate metabolism of the body. The exact mechanism by which the nervous system produces this change is not apparent, but it may be through an effect produced in the functions of the liver. It is well known that brain-workers are particularly liable to colds and other infections, and Prof. Suk suspects that this liability may arise from the reduction of their blood-sugar.

THE CHANCELADE SKULL.—In *Annals of Eugenics*, vol. 1, Parts 3 and 4, Mr. G. M. Morant compares, by means of modern statistical methods, the craniometrical features of the skull found in 1888 by Féaux and Hardy near Raymonden, Chancelade, with those of Fürst and Hansen's series of Greenland Eskimos. He concludes, in agreement with the suggestion of Testut, and contrary to Keith's recent verdict (*Man*, 1924), that the Magdalenian skull is not more removed from the mean type of the modern inhabitants of Greenland than many individuals picked at random from that population are likely to be. In accordance with the view that the Chancelade individual was closer to the Eskimo than to the modern English, he sees justification for assuming that, in the Magdalenian period, a race of hunters existed in southern Europe, which migrated northwards following the reindeer, or was pushed to the fringe by other and invading races. Excellent photographs, taken with a telephoto-lens to reduce distortion, accompany the study.

POTTERY FROM CHANCAY, PERU.—A further study of the Uhle Collections of Peruvian pottery in the University Museum appears as vol. 21, No. 7, of the *University of California Publications in American Archæology and Ethnology*. Mr. A. L. Kroeber now describes the pottery from Chancay which was obtained by Dr. Uhle in graves on five sites described in his field notes, part of which form an appendix to the present publication. Five successive styles are represented: black-on-white, a style known as that of Chancay and the latest in date; three-colour geometric, epigonal (three and four colour), white-on-red, and the interlocking style. White-on-red is a hitherto undescribed style which is definitely Central Peruvian. The interlocking type, of which the most common design has the typical outline of complementary animal heads with worm-like bodies having serrated edges, is undoubtedly textile in origin. Certain vessels present affinities with the Proto-Nasca of Ica, and, further, round lumps of adobe characteristic of Proto-Nasca construction were also found with the Chancay burials. Dr. Uhle has demonstrated the relation of Ica in the north and Truxillo in the south. Notwithstanding the wide geographical separation of the two styles, Chancay, lying half-way between the two, appears to bridge the gap by a civilisation of the same general character, and suggests a cultural stage all over Peru at a remote epoch antedating Tiahuanaco. The importance, undoubtedly religious, of this design was indicated by the discovery of a painted wall belonging to a small terrace building on an artificial base. The wall was 23 m. long and 1·6 m. high at its best-preserved part, and was painted in four colours with outlines of the textile design.

THE FOX INDIANS.—The fortieth annual report of the Bureau of American Ethnology (1918–19), which has just been issued, contains, in addition to the report of the chief of the Bureau, five accompanying papers by Dr. Truman Michelson based upon material gathered fourteen years ago and supplemented by later information dealing with the Fox Indians of Iowa. Each paper is a Fox text written out in the current syllabary by one of the Indians and afterwards phonetically restored, accompanied by an English translation and ethnological and linguistic notes by the author. The first paper deals with the mythical origin of the White Buffalo dance, and contains, in addition to the information about Fox ritual, some interesting data bearing upon changes in custom and the social and religious outlook of the Indians. The reverent observance of religious rites still to be found among the older men is no longer characteristic of younger generations, who attend the dance purely for social purposes and to get something to eat. A note on mortuary customs and beliefs is important for its detail and for the light it throws on observances in connexion with behaviour after death of a husband or wife and remarriage. Of the remaining three papers, two deal with Fox religious societies, and the third, an autobiography of a Fox woman, is unique. It begins with her earliest recollections, and from her eighth year gives particulars of her introduction to the various household duties which fall upon the woman in the Indian family. At nine years she helped her mother in the planting; at ten in washing clothes and cooking, and in cutting and gathering wood; at eleven she learned to make bags, and so on. One of the most interesting features of the story is the importance of the mother's brother, which becomes especially marked after marriage, when the father ceases to function in relation to his daughter and his place is more than taken by the uncle. For example, the uncle advises his niece as to her behaviour after divorce, and when her husband dies instructs her in the mourning ceremonies and the observances which secure release from the death ceremonies. Apparently this function of the maternal uncle has nothing to do with matrilinear descent, and cannot be regarded as a survival of that system, though the Foxes are now patrilineal.

THE ALIMENTARY CANAL OF SCORPIONS.—In the current issue of the *Quarterly Journal of Microscopical Science* is a detailed account by Prof. E. N. Pavlovsky and Prof. E. J. Zarin of their studies on the structure and functions of the various parts of the alimentary canal of scorpions. The authors have not been able to investigate the physiological properties of the maxillary glands, which it is believed may produce a proteolytic ferment. The food—the juices and muscles of arthropods and of earthworms—passes

into the stomach of the scorpion, where it is acted upon by pepsin, trypsin, chymosin, and lipase. The mid-gut of scorpions is of insignificant volume as compared with the cavities of the liver tubules, and it is evident that the latter are of the greatest importance. They contain two kinds of cells, secretory cells, producing ferments which act on proteins, fats, and carbohydrates, and absorptive cells. The authors suggest that the liver also plays a part in excretion, the presence of brown granules in its cells being cited as evidence. The intestine appears to play little or no part in the digestive processes.

LUMINOUS FISHES AND CEPHALOPODS OF THE MEDITERRANEAN.—Number 9, vol. 2 (Biology), A. 12, of the report of the Danish Oceanographical Expedition, 1908–10, to the Mediterranean and adjacent seas includes an extremely interesting account of the Mediterranean Sternoptychidæ by P. Jespersen and Å. Vedel Tåning (Copenhagen: Andr. Fred. Høst and Søn, 1926. 35s.). In their study of these peculiar luminous fishes, much light is thrown on their breeding, life-histories, and migrations. Many of these fishes tend to move to a greater depth with increasing age, the adults often occurring naturally at a depth of more than 1000 metres, whereas the post larvæ are found much higher up. The photophores in this group are important as a means of classification, but in many of the genera these do not appear until late in post-larval life or after metamorphosis, and there is often an enormous alteration in general appearance and also a great reduction in length, as, for example, in *Ichthyococcus ovatus*. Dr. Degner's important monograph (C. 1), which is also included in No. 9, vol. 2, of this report, on the cephalopods deals also with a group which in many forms is luminous, but in this case comparatively few are from great depths. The majority occurred between the surface and a depth of 65 metres, and mainly belonged to the Decapoda. A single specimen of an adult Argonauta was obtained in the Mediterranean and one of Spirula just outside, close to Gibraltar. Many young forms of various species were taken and a few new species are described, including *Mastigoteuthis Schmidti* and *Desmoteuthis Thori*, both from waters of 2700 metres depth.

AMPHIPODS AND DIATOMS FROM THE DANISH OCEANOGRAPHICAL EXPEDITION.—In Number 9, vol. 2 (Biology), D. 5, of the report of the Danish Oceanographical Expedition, 1908-10, to the Mediterranean and adjacent seas (Copenhagen: Andr. Fred Høst and Søn, 1926. 35s.), Dr. K. Stephensen finishes his account of the Hyperiidea-Amphipoda, of which Parts 1 and 2 have already appeared. A large portion of the present work is taken up by the valuable synopsis of the Hyperiidea in which the Mediterranean species, eighty in all, are fully discussed. The author finds that there do not seem to be any species endemic to the Mediterranean, nearly all being found also in the Atlantic, and there seem to be scarcely any differences between specimens from the two areas. The Hyperiidea are almost exclusively oceanic, and many are found over great depths, some never rising above a 300-metre level; but of these deep-water forms few enter the Mediterranean. The species found there belong almost exclusively to the surface layers. Prof. Pavillard, in the same volume (J. 4), gives an interesting account of the planktonic diatoms which in these regions are really fairly well known, and his investigations show few new species but much new matter as regards distribution. The absence or great rarity in the Mediterranean of certain species common and well known in the English Channel and outside is striking. Thus *Hyalodiscus stelliger* apparently does not occur, *Paralia sulcata* is very rare, and *Thalassiosira gravida* is replaced by *T. rotula*. The summaries of the larger genera such as Chætoceros, Rhizosolenia, and Coscinodiscus are instructive and helpful, and as an up-to-date guide to pelagic diatoms the whole work is extremely valuable.

MICRO-ORGANISMS IN INDUSTRY.—In his presidential address to the Royal Microscopical Society, Mr. A. C. Chapman gave an account of some of the Fungi imperfecti—torula, mycoderma, ooidia—and their activities (*Journ. R. Micr. Soc.*, vol. 46, Part 1). He referred to a yeast-like organism, isolated by Prof. Lindner of Berlin in 1916 from the sap which had exuded from a birch tree, which was able to grow freely on the surface of carbohydrate solutions containing ammonium salts and to form a thick greasy film This film when separated and dried was found to contain 18 per cent. of fat, 31 per cent. of crude protein, and 43 per cent. of carbohydrates, so that, given a cheap source of carbohydrate and ammonium salts, it was evident a food product rich in fat and protein could be produced in large quantity. Mr. Chapman isolated a similar organism in 1917, and reports that the product of its activity contained about 50 per cent. of crude protein and up to 10 per cent. of fat, and that when pressed it formed cakes having the odour and flavour of cream cheese. He points out that if an efficient biochemical process were discovered for the conversion of cellulose into sugar, the production of a synthetic food product on a large scale would become practicable perhaps even under peace conditions. He quoted a sentence from a lecture which Hayduck delivered in Berlin in 1916—"when we can convert our evening papers into sugar so rapidly that we are able the following morning to eat the albumen prepared therefrom, then indeed we shall have solved one of the greatest problems of the century." Mr Chapman advocates the founding of a National Institute of Industrial Microbiology for research on micro-organisms which play an important part in industry, for the training of teachers of microbiology, and for maintaining a collection of pure cultures of micro-organisms for industrial purposes.

AUSTRALIAN RIVER BASINS.—A map of Australia, showing the extent of the drainage areas of the various rivers, has been published by the Bureau of Meteorology of the Commonwealth of Australia. The positions of river gauges and flood report stations are also shown. The map should prove useful in connexion with the flood warning service of the Bureau. In times of heavy rainfall, it will facilitate the issue and distribution of flood warnings to the districts concerned. The map is on the scale of 200 miles to an inch and a half.

THE CLIMATE OF HELWAN.—A discussion on the above by Mr. L. J. Sutton, Director of the Egyptian Meteorological Service, has been issued by the Ministry of Public Works, Egypt, as Physical Department Paper No. 20 (Government Publication Office, Cairo, price P.T. 10). The present report deals with the observations of the years 1906–20, and fifteen years are said to be probably sufficient in a climate like that of Helwan to give a fair representation of a true normal, except perhaps for rainfall. The scheme for the report was commenced by Mr. Knox-Shaw, but, owing to his appointment as Radcliffe Observer at Oxford, the work of preparing the report was handed to Mr. Sutton. The climate of Helwan is essentially of the Saharan desert type. There is a short winter, December to February, when the nights are cold, averaging 9° C., and the days comparatively warm, averaging about 20° C. The temperature never falls to the freezing-point, the lowest ever

recorded being 1·6° C. Nearly 8 hours of sunshine are enjoyed each day, and normally there are only 3 days of rain in each of the winter months, but sometimes thunderstorms occur with heavy rain. Summer commences in June and lasts until the end of September; from June to August there are more than twelve hours of sunshine a day, the temperature reaches 35° C. on the average during the daytime and falls to about 21° C. at night. In the early part of summer, temperatures of 40° C. are not uncommon, and on two occasions a temperature of 46° C. (115° F.) has been recorded. The summer is rainless, and there is scarcely any rain from May to October. Tables and diagrams with detailed accounts are given of all the meteorological elements. The work adds much to our knowledge of weather conditions in this part of the globe.

WEATHER AND AGRICULTURE.—Responsible United States officials engaged in the Weather Bureau, the Bureau of Agricultural Economics, and the Forest Service have co-operated in producing a discussion, No. 918, published by the United States Department of Agriculture (Washington: Government Printing Office, price 20 cents). It is asserted that so early as 3000 years B.C. man was a tiller of the soil and gathered a harvest. Since then the history of agriculture and the weather has been contemporaneous with that of civilisation itself. The development of agricultural education such as the establishment of agricultural colleges and experimental stations is dealt with. The influence of the weather and especially the control of weather by cyclones and anticyclones is referred to and the adjustment of agriculture to climate, soil condition and topography. Maps are given showing the distribution of rainfall over the globe, and the natural vegetation, and also air isotherms over the world for January and July. Referring to the rapidly increased population in recent times, the unoccupied arable land of the world has become gradually occupied until to-day very little remains in regions with healthful climates. It is stated that the United States, with only about 5 per cent. of the world's population, produces one-seventh of the world's cattle, one-fifth of its wheat, and three-fourths of its corn. Rainfall and crop growth is gone into with considerable detail, also the temperature influence on crop distribution. It is asserted that where climate and other conditions permit of mixed farming, the weather hazard is very much reduced. Many matters such as weather and the railroads and details intimately associated with salving the crops are of much interest.

METEOROLOGY AND GEOPHYSICS IN POLAND.—In Communications Nos. 1-18, Institut de Geophysique et de Meteorologie de l'Université de Lwów, Prof. H. Arctowski and eight collaborators publish a series of papers on meteorological, astronomical, and geophysical subjects. Eight papers contain discussions of temperature variations observed during the years 1910-1919 at Arequipa and at a number of widely separated stations. These temperature variations are employed to show the distribution and movement of "thermo-pleions" (areas of positive departure of temperature from the normal) and "antipleions" (areas of negative departure) in Egypt, Hawaiian Islands, India (the Deccan), New Zealand, Peru, Philippine Islands, Russia, and Scandinavia. The agreement between the Arequipa or standard type of thermo-pleionian fluctuation and that prevailing in the Deccan is found to be particularly striking during the ten years of observation. Four other papers deal with pyrheliometer observations. During 1924 a number of these observations were made by three different methods at Pozyzewska (altitude 1406 metres) in the eastern Carpathians for the purpose of finding a suitable site for a solar observatory. The remaining contributions relate to (1) The dissimilarity of the variation of the frequency of sunspots observed north and south of the sun's equator, and the desirability of considering sunspot statistics for each hemisphere separately; (2) the anomalies in the measurement of rainfall and the exposure of rain-gauges; (3) the determination of the "geothermic" degree from observation of the temperature gradient existing in certain petroleum wells in Poland; and (4) the occurrence of potassium salts in Poland. The above series of papers have been published in the *Kosmos*, vols. 46-50, 1922-1925.

MAGNETIC VARIATION IN NORTH AFRICA.—The secular magnetic variations at Tunis, Carthage and Malta are considered by Dr. L. Palazzo in the *Memorie della Pont. Accademia delle Scienze Nuovi Lincei*, vol. 8, 1925. Dr. Palazzo himself made observations of all three magnetic elements at Tunis and Malta in 1890, and has recently repeated the observations. In 1890 he also measured the horizontal intensity at Carthage. In this memoir he summarises other observations available for the three stations, and constructs graphs showing the secular variation of declination, dip and horizontal intensity; for Tunis the graphs extend from 1875 to 1925, in which time the declination has decreased by about 5° to its present value of about 7° 20′ E. The Carthage declination and dip graphs extend from 1820 to 1905, and are in general agreement, as regards secular variation, over the period in common with those for Tunis, as would be expected from the proximity of the stations. The Malta data extend from about 1820 to 1925, and show a decrease in E. declination from 17° 20′ to 5° 40′.

VELOCITY OF DETONATION FOR EXPLOSIVES.—The explosives in general use in fiery and dusty mines belong to the class of detonating explosives. It is known that the ignition of inflammable gases in the neighbourhood of the borehole depends in large measure on the velocity of detonation. It is therefore of great importance to find a method of determining this velocity for the practical explosives used in mines. To determine this velocity, very small intervals of time of the order of a millionth of a second have to be measured. A method suitable for doing this is described by E. Jones in the Safety in Mines Research Board, Paper No. 22 (London: H.M. Stationery Office, 1926. Price 9*d*. net). The method is an electrical one. It depends on the partial discharge of a condenser through a known non-inductive resistance. The time of the discharge is the time taken by the detonation wave to travel between two points at which the circuits are broken. The times computed were tested with mechanical arrangements which gave time intervals of the order 10^{-4} sec. to 10^{-6} sec. The results were concordant for long fuses, but unsatisfactory when the trinitrotoluol fuse was only about 10 cm. long. The discrepancies in this case were traced to electrical phenomena due to detonation, and were overcome by removing the break-points of the circuit to a distance from the detonating explosive. Consistent results were now obtained, although the fuse length was reduced to 2 cm. The difference between the results and that given by the Mettegang method for metre lengths of the explosive was rather less than 3 per cent. The latter method, however, only gives the average velocity over the metre. The agreement consequently is satisfactory. Further researches are in progress.

Oxford Meeting of the British Association.

PROVISIONAL PROGRAMMES OF SECTIONS

WE print below short accounts of the proceedings of the various sections of the British Association at the Oxford meeting to be held on August 4-11. For these particulars we are indebted to the recorders of sections. The statements are brief, but it is clear that interesting and stimulating sessions have been arranged which should do much to make the Oxford meeting memorable in the history of the Association.

SECTION A (MATHEMATICS AND PHYSICS)

The coming meetings of Section A (Mathematics and Physics) are likely to be filled with interest. Apart from the attractions of Oxford itself with its own important schools in these subjects, there are two other contributing factors. First, the list of foreign guests is a particularly interesting one, the visitors including Bohr, Born, Carathéodory, Franck, Runge, Siegbahn, Wien and Zeeman, in addition to well-known representatives of the Dominions overseas. Secondly, a full programme has been arranged for a subsection in mathematics, meeting for three mornings. This should attract many mathematicians who may have refrained from attending previously owing to the minor part that this subject has played in the programme of the Section in recent years.

In physics, in addition to full accounts of work being carried out in the laboratories of Prof. Townsend and Prof. Lindemann, papers will be read by Sir Ernest Rutherford, Sir William Bragg, Prof. W. L. Bragg, and others. On Monday, August 9, Prof. A. Fowler's presidential address will be followed by a discussion, in which most of the foreign guests are expected to take part. A joint discussion with Section B (Chemistry) on the mechanism of homogeneous chemical reactions should enable many physicists to learn something about a subject in which few of them have specialised.

In mathematics, in addition to a full morning on integration and trigonometrical series, special lectures from Dr. T. M. Cherry, Mr. F. P. Ramsay, Mr. M. H. A. Newman and Mr. T. W. Chaundy have been arranged, and contributions are expected from Sir George Greenhill and Prof. E. A. Milne. Lastly, a paper by Mr. Stratton on the recent eclipse observations, and by Prof. Turner on the coming total eclipse in England, should make a wide appeal throughout the Section.

SECTION B (CHEMISTRY).

Prof. J. F. Thorpe will deliver the presidential address to Section B (Chemistry) at 10 A.M. on Thursday, August 4, and will take as his subject "The Scope of Organic Chemistry." Two discussions have been arranged—one (a joint discussion with Section A) on the mechanism of homogeneous chemical reactions and the second one on tautomerism. Prof. W. N. Haworth is to submit a paper on modern views on the structure of the disaccharides, and Mr. J. J. Manley is to describe the work he has conducted on the union of mercury and helium. Of the foreign visitors, Prof. J. Backer is reading a paper on separation and racemisation of simple optically active compounds, and Prof. H. ter Meulen is to describe the uses of hydrogenation in organic analysis. A novel feature of the work of the section will be a paper by Mr. A. Chaston Chapman and Dr. H. J. Plenderleith on an examination of King Tutankh-Amen's cosmetic.

SECTION C (GEOLOGY).

The communications promised for Section C have been so numerous that the time available for presentation and discussion may prove inadequate. Although the meetings of the Section have been extended beyond the normal number, selection of papers has been necessary; yet the programme as at present arranged covers a very wide range of interest, and, so far as possible, kindred studies have been grouped. It is invidious to pick out any papers for special mention, but, to take a conventional subdivision of the subject-matter into mineralogy and petrology, palæontology and physical and stratigraphical geology, the following notes may suffice to convey some idea of the scope of the programme.

The atomic structure of silicate minerals has proved difficult up to the present, but a paper on certain of these minerals is promised, while communications on the textures and structures of igneous rocks will also be received. Sedimentary petrology is also represented. In the realm of palæontology the faunas and classification of the faunas of certain epochs in the past will be considered, notably those of Cambrian and Silurian times; the fauna of more recent deposits, local to Oxford, will be represented by an exhibit which may be consulted during the meeting. Physical and stratigraphical geology will naturally figure largely, and here interests range in time from pre-Cambrian to recent, and in space from England to the farthest confines of the British Empire.

Two important discussions will be held: one on problems connected with the Thames gravels and their fossil contents, and the other in conjunction with Sections D (Zoology) and K (Botany) on the "Conception of a Species." In all branches of natural science the definition of units is necessary, and a biological unit is as fundamental as a unit of length or of temperature. Unfortunately the species, as a unit, has not proved capable of rigid definition, and, from time to time, it is obligatory to take stock of the position. The discussion therefore should be of value in stating the present ideas on this fundamental biological concept.

In the interests of those who are beginning research work and desire some knowledge of technique, a series of short descriptions of certain research methods will be given by workers who have taken special interest in the development of such processes. Demonstrations have also been arranged in illustration.

A most important part of the work of the section centres round the excursions. The local secretaries have so arranged their work that this part of the programme has been in the hands of Mr. C. J. Bayzand, who has drafted an excellent series of half-day and whole-day visits to the neighbourhood. Ill-health may prevent him from being present on these trips, but it is hoped that he may be recovered in time to reap the reward of his sowing. On present showing, then, the Oxford meeting, so far as Section C is concerned, promises to be an excellent one from every point of view.

SECTION E (GEOGRAPHY).

Much attention has been directed of late to economic and social problems associated with the awakening of Negro Africa. Their complexity defies unanimity on methods of administration and development. The president of the Section—the Hon. W. Ormsby Gore,

Under Secretary for the Colonies—following his recent investigations in East and West Africa, will speak on "The Economic Development of Africa and its Effect on the Native Population." This will be followed on the afternoon of Thursday, August 5, by an important joint discussion with Section H (Anthropology) on "The Effect on African Native Races of Contacts with European Civilisation." Among those who will take part in the discussion may be mentioned the Rev. Edwin Smith, Sir Frederick Lugard, Capt. G. Pitt-Rivers, Prof. J. W. Gregory, Sir James Currie and the Hon. Hugh Wyndham.

In Britain, of recent years, one of the most striking applications of geographical study has been the attempt consciously to adjust conditions of life and industry to locality, especially in urban areas. Town planning and regional surveys have in a measure reacted on the character of some of the geographical research in the universities. Two papers, one on London and the other on Manchester, illustrate what is being done in the several university schools of geography, and will form the basis of a general discussion on "Regional Work in Geography."

Several papers present historical aspects of geographical science: Elizabethan theodolites and astrolabes, by Dr. R. T. Gunther; the 'Pantometria' of Leonard Digges, by Mr. A R. Hinks; the British Isles in the nautical charts of the fourteenth and fifteenth centuries, by Mr. M. C Andrews; roads on English and French maps at the end of the seventeenth century, by Sir George Fordham. The numerous implications which the geographical study of a region involves is well represented by such contributions as Dr. D. G. Hogarth's on "Our Near Eastern Borders," Prof. Lyde's on modern markets for Canadian wheat, and Mr. Dunlop's comparison of Queensland and Jamaica.

Geographical excursions have been arranged to Brill, the Cotswolds, the central Chilterns and the Goring Gap.

Section F (Economics).

In his presidential address to Section F (Economics), Sir Josiah C. Stamp will deal with "Inheritance as an Economic Factor"; it is expected that Prof. Rignano (Italy), Dr. Hugh Dalton, M P, Prof. Edwin Cannan and others will take part in the discussion.

A distinctive point of view upon "Collective Bargaining" will be presented in a paper by Sir Lynden Macassey, in which he will argue that effective collective bargaining is the basis of industrial stability and that recent events have shown the absence of this condition in Great Britain. Mr. Flux, of the Board of Trade, will deal with the markets of the chief British export industrial centres and will use material which has not previously been available for this purpose.

A discussion of peculiar present-day importance will take place upon currency problems, and it will be opened by Prof. Gregory in a paper dealing with the gold standard.

In addition to such topics of outstanding interest as those mentioned above, the Section is to take part in a discussion on a "Survey of the Limits of Agricultural Expansion," which will form the subject of Sir Daniel Hall's presidential address to Section M (Agriculture)

Section G (Engineering).

The programme of Section G includes discussions on subjects of very varied interest. The president, Sir John Snell, chairman of the Electricity Commission, in his address will deal with the important subject of electric supply, its recent and probable future development. Following the address Mr. Kennedy will read a paper on the distribution of electric energy, and Mr. Borlase Matthews will discuss the use of electricity in agriculture; some phenomena of conduction will be discussed by Prof. Cramp. Refrigeration, particularly in relation to food preservation and transport, is a subject of scientific and practical interest, and two papers by Dr. Ezer Griffiths and Prof. C. F. Jenkin are to be followed by a discussion in which Sir William Hardy and Sir Richard Glazebrook will take part. The papers will describe small plants that have recently been developed and experiments carried out in the laboratory and on four ships. In connexion with this discussion, a number of small plants will be working in the University Engineering Laboratories.

Recent developments in aircraft are to be discussed. Mr. Wimperis will deal with the 'rotating wing' and describe experiments and the attempts that have been made to use the device for sustentation purposes; the possibilities of its use will be discussed. The researches that have been carried out in connexion with the development of a compression ignition engine for aircraft and burning heavy oils will be described by Mr. H. D. Pye. The problem of producing a fuel jet which penetrates the compressed gas sufficiently to give adequate mixing of air and fuel, and at the same time to obtain sufficient pulverisation and combustion in the short time available, will, *inter alia*, be dealt with. It has been found possible to burn 70 per cent of the oxygen in the cylinder, but to get perfect mixing at high speeds is extremely difficult. The possibility of eliminating all complications and danger incidental to electric ignition makes it worth while to attempt to develop a compression ignition engine sufficiently light for aircraft purposes. The use of light alloys in aircraft is becoming increasingly important, and the paper by Mr. Bengough and Mr. Sutton will describe the anodic oxidation process which has been successfully developed to render these alloys immune from surface corrosion.

Experiments on materials subject to complex stress conditions will be discussed by Prof. F. C. Lea and Mr. S. Timoshenko.

The microscopic and macrographic methods of detecting the sulphur bacterium *Beggiatoa Alba*, and investigations in which its presence indicates sewage pollution, will be described by Prof. Ellis. The cause of the blackening of the river sands below water level in the Clyde Estuary has been investigated, and it has been shown that this is not due to sewage pollution but to the formation of ferrous sulphide by a reaction between the ferruginous constituents of the sand and the hydrogen sulphide liberated by bacteria which consume the animal and vegetable remains on the shore. A paper by Mr. Edgar Morton on the "Composition and Texture of Sandstone and Limestone in relation to Strength and Durability" should prove of interest to geologists, engineers, architects and builders Papers dealing with the distribution of pressure in turbines and the influence of voltage harmonics on power factor correction are to be given.

Section H (Anthropology).

In Section H (Anthropology) one of the most important features of the programme will be the exhibition of the human skull found in association with Mousterian implements by Miss D. A. E. Garrod near the Devil's Tower, Gibraltar. In view of the conditions of its discovery and its possible relation to the skull of Neanderthal type found at Gibraltar in the middle of the last century, it should give rise to an important discussion. Miss Garrod's discovery will give added interest to Sir W. Boyd Dawkins'

paper on the range of the Neanderthal race on the Pleistocene continent.

The Section will engage in two joint discussions with other sections. The first, with Section E, on the effect on African races of contact with European civilisation, arises directly out of Mr. Ormsby Gore's presidential address to Section E, and will be opened for Section H by the Rev. E. Smith, who will be followed by Sir Frederick Lugard, should his engagements permit. The second joint discussion, with Section D (Zoology) and Section J (Physiology), on mental and physical aspects of heredity, will be opened by Dr. C. S. Myers, to be followed by Profs. Ruggles Gates and Julian Huxley. Sir William Ridgeway will open a sectional discussion on "The Origin of the Scot."

Among a large number of communications making up the remainder of the programme mention can be made of a few only. Sir Arthur Evans on "The Shaft-Graves of Mycenæ and their Contents in relation to the Beehive Tombs" is likely to prove provocative of animated discussion; Mrs. Zelia Nuttall, the distinguished American archæologist, in dealing with the ancient calendar systems of America, will give the Section what is virtually a summary of the results of her life's work. The excavations of the British School at Athens during the past three seasons will be described by Mr. A. M. Woodward, the Director, and Mr. W. A. Heurtley, the latter dealing with his own investigations in Macedonia. Recent excavations in Mesopotamia will be covered by Mr. C. L. Woolley on his recent work at Ur, and Prof. Langdon on work at Kish, skulls from the latter site being described by Mr. L. H. D. Buxton. In Egyptian archæology Miss Gardiner and Miss Caton-Thompson will describe their recent work on the geology and early archæology of the Fayum, and Sir Flinders Petrie will put forward for discussion his views on the prehistoric relations of Egypt and the Caucasus. An important paper by Mr. Gordon Childe will deal with the Terramare and the Hungarian Bronze Age, in which he will carry further his previously published work on the prehistoric archæology of Central Europe.

An interesting series of papers dealing with physical anthropology must be passed over, but in conclusion mention must be made of Miss Alford's communication on 'the ritual dance,' in which she discusses the ritualistic origin of a number of English folk-dances and cites continental parallels. The paper will be illustrated by dances performed by members of the English Folk-Dance Society.

Section I (Physiology).

By an unfortunate chance the British Association meetings this year fall at the same time as the (triennial) meetings of the International Congress of Physiology, which will be held at Stockholm on August 3-6. Although the Section may, in consequence, lack a certain number of British and of foreign workers, the sectional programme is quite a full one. The subject of the presidential address is "Function and Design": to this question Prof. Leathes is bringing a fresh outlook, notably from recent work on molecular structure and orientation, with a special consideration of the arrangements at the limiting surfaces and membranes of the organism.

As was suggested in the columns of NATURE of May 29, p. 747, the lecture by Dr. J. S. Haldane on "Acclimatisation to High Altitudes" is of particular interest, in that a reply to Prof. Barcroft's recent publications may confidently be expected, and a consideration of the physiological observations and problems connected with the climbs on Mount Everest. In the joint discussion with Section D (Zoology) on the value of tissue-culture in biology, members will have the first opportunity in England of hearing from Prof. Ch. Champy, of the Sorbonne, an account of his technique and the results he has obtained in this work. The discussion will be opened by Dr. H. M. Carleton, who is in charge of the Department of Histology at Oxford.

A symposium on the 'machinery' whereby a posture is set up or maintained, will allow an exchange of observations and opinions between clinicians and laboratory workers, who have a common interest in this problem, though their paths of approach may be entirely different. Of wide interest, again, is Sir J. C. Bose's lecture on "The Pulse-Beat of Plant and of Animal," while among the more specialised papers are contributions on colour-vision, on biochemistry, and on visceral sensation.

Section J (Psychology).

Applied psychology figures prominently in the programme of Section J (Psychology); thus the presidential address by Dr. J. Drever is entitled "Psychological Aspects of our Penal System." A whole session is given to such industrial questions as accidents in industry, restriction of output, and the judgment of value of individual advertisements. There is also a lecture on recent progress in vocational selection. These papers will give an account of some of the activities of the National Institute of Industrial Psychology.

Medical psychology is represented by three papers, namely, personality and value, a method of self-analysis, and heredity and environment in the production of morbid mental reactions. That psychologists are paying attention to heredity is shown by their participating with Sections D and H in a joint discussion on heredity in its physical and mental aspects.

It is gratifying to note that all past presidents of the Section are contributing papers: Prof. C. Lloyd Morgan, "Individual and Person"; Dr. C. S. Myers, "Heredity in its Physical and Mental Aspects"; Prof. Cyril Burt, "Estimations of Temperament and Character"; Prof. W. McDougall, "An Experiment supporting the Lamarckian Hypothesis" and "Intelligence in Rats". Prof. C. Spearman, "The Origin of Error."

Of the more academic papers mention should be made of one by Prof. Rignano of Milan on "La psychologie dans ses Rapports avec la Philosophie et avec la Science," one by Prof. Michotte of Louvain on observation and analysis of mental facts, one by Dr. Aveling on the psychogalvanic phenomenon, and one by Dr. Banister on the localisation of sound. A paper by Dr. Maxwell Garnett on the psychology of patriotism should prove of wide interest; also one by Mr. F. C. Bartlett, Director of the Cambridge Psychological Laboratory, on the social psychology of leadership.

Section K (Botany).

Owing to the lamentable death of Mr. W. Bateson, Section K (Botany) will meet at Oxford under the presidency of Prof. F. O. Bower. The Section will participate in a discussion on "The Conception of a Species" with the Sections of Geology and Zoology. Within the Section there will be a discussion on sex-determination in plants, which will be opened by Dame Helen Gwynne-Vaughan and contributed to by Dr. Heslop Harrison, Prof. H. Kniep, and Miss Cayley. Prof. J. H. Priestley will initiate another sectional discussion on the scientific principles underlying vegetative propagation, a subject on which a good

deal of light has been thrown recently. The popular lecture will be given by Sir Frederick Keeble on "The Nervous System of Plants."

A large number of papers representative of different branches of botany have been included in the programme, the subject of genetics being particularly well represented this year A notable feature of the Oxford meeting will be the attendance of a larger number of distinguished foreign botanists than has been the case in recent years. All of them are contributing actively to the programme As in the last few years, there will be a Sub-section of Forestry, which will be linked with Section K. The Sub-section also has a very full programme, and will be presided over by Lord Clinton.

SECTION L (EDUCATION).

Section L (Education), under the presidency of Sir Thomas Holland, opens its session at Oxford on Thursday, August 5, with several papers dealing with the place of history of science in education Dr. Charles Singer and Prof. Cecil H. Desch will discuss the subject from the point of view of its value as a humanising element in the teaching of science at university or school. Dr. Gunther will demonstrate the educational value of the Lewis Evans' Collection of historic scientific instruments at the Old Ashmolean Building.

Later in the meeting the more recent advances in educational science will be discussed: the development in the general conception and scope of education during the last twenty-five years by Prof. T P. Nunn; the education of children under eleven years of age by Miss Margaret Drummond; developments in methods of teaching by Dr. M. W. Keatinge; the organisation of education by Prof. Strong; and educational psychology by Prof. C. Burt. The Section will be invited to discuss scholarships—methods of award and their effect on the present system of education—by Mr. William Hamilton Fyfe. Important results of a recent investigation into the claims of the kinema and of radio to be potent agencies in modern education will be brought before the Section by Dr. C W Kimmins, Mr. G. T. Hawkin, and Dr. J C Stobart The public school system is to be reviewed by Mr Ronald Gurner, Mr. W. W. Vaughan, Mr. M. L Jacks, Dr. Crichton Miller, and Mr. F. J. R. Hendy Its relation to national life, its psychological interpretation, its value as a training in community life, together with a critical appreciation of its economic position, are some of the features of the papers to be read.

On Thursday, August 5, a joint session of Section L (Education) and M (Agriculture) will be held in the hall of the Union Society to discuss the educational training of boys and girls in secondary schools for life overseas. Various aspects of this question will be dealt with by Sir A Daniel Hall, Hon. W. Ormsby-Gore, Sir Halford Mackinder, Miss Gladys Potts, Sir John Russell, Sir Alfred Yarrow, and others. This meeting has been organised for the purpose of directing public attention to the results of an investigation carried out by a special committee, appointed by the Council in 1923. Two reports have already been issued. The Committee hope this year, through this meeting, to emphasise the most important results of their investigation, namely, first, that a growing and widespread demand exists in the Overseas Dominions for boys and girls well educated with an agricultural bias; secondly, that Great Britain has an increasing need of finding healthy and profitable employment within the British Empire for a large number of her sons and daughters; and thirdly, that practical studies of all kinds, especially those related to agriculture, possess a training value far too little realised by parents and by educational authorities.

SECTION M (AGRICULTURE).

The Section will meet under the presidency of Sir Daniel Hall, whose presidential address on the limits of agricultural expansion will form the basis of a joint discussion with Section F (Economics), at which the speakers will include Lord Bledisloe, Sir Thomas Middleton, and Mr. R. J. Thomson Sir Daniel Hall will also open a joint meeting with Section L (Education) on training for overseas life, at which several distinguished people have promised to speak, and at which it is hoped that the president of the Association may be present.

In addition to these two joint discussions, much time will be devoted to sectional discussion, so that the number of individual papers which are being presented is smaller than usual. It is proposed at a sectional meeting to review the present position of agricultural education in Great Britain, and to consider the methods adopted to make available to those engaged or about to be engaged in the agricultural industry the results of scientific research. Another session will be devoted to possible improvements in cultivation methods, both hand and machine, which is a subject with very important practical and economic bearings at this time when the position of arable land farmers is so precarious.

Other subjects of more technical interest which will occupy the Section are those of soil classification and the nutrition of dairy cattle, in which connexion a paper by Sir A Theiler and Drs Green and Du Toit on the minimum mineral requirements of cattle should be of great interest This South African work forms an interesting complement to that carried out at Aberdeen, Cambridge, and elsewhere in Great Britain.

Messrs. Sutton of Reading have kindly invited members of the Section to visit their seed establishment, and a visit will also be made to the Agricultural Department of the University of Reading

Universities of the British Empire.

THE universities of the British Empire are parts of a system dependent for its equilibrium and orderly progress in changing conditions on adjustments of factors making for integration and differentiation. The Congress of Universities of the Empire, which met last week at Cambridge, represents an adjustment on the side of integration. A glance at the lists [1] of subjects discussed at the first and second Congresses, 1912 and 1921, brings out the fact that the subjects of last week's discussions are, like those of 1912, but to an even greater extent, concerned directly with co-operation between universities, whereas the programme of 1921 was of a more open and exploratory character Of the seven subjects of the plenary sessions, five, of the four subjects of sectional meetings, three, were directly and obviously concerned with the question as to how universities in different parts of the British Empire may most effectively help one another. Congresses are sometimes criticised adversely as "leading to nothing," especially where, as in the present instance, the discussions do not culminate in 'resolutions.' It remains to be seen whether the third Congress of the Univer-

[1] "Universities Yearbook, 1926," pp. 12 and 13.

sities of the Empire will merit this criticism, but definite practical suggestions for immediate action were not lacking.

Lord Balfour opened the proceedings of the first session on Tuesday, July 13, the subject of discussion being "The State and the University." The new problems confronting universities arise, he pointed out, not from the social changes of the time so much as from the growth of modern knowledge and its paradoxical correlative, the growth (due to specialisation) of modern ignorance. The former has brought in its train an enormous increase in the expensiveness of the material plant indispensable for the pursuit of the study of science and urgent pressure on the State, and, through the State, on the universities, to develop the applications of science to the problems of industry. In the absence of other sufficient available means of obtaining the wherewithal to provide and maintain the requisite buildings and equipment, the universities of Great Britain have sought and obtained State subsidies, and, even where these have not been ear-marked for work in applied science, have inevitably aroused a natural and pardonable, but dangerous, instinct on the part of the State to control and supervise. Hitherto that instinct has not found expression in Britain in any serious menace of excessive interference, but the universities must ever be watchful lest they betray their trust to cherish the spirit of disinterested research, a dereliction which would in the long run be fatal to the very industrial interests it might be supposed to serve. The sphere in which the universities can at present most fruitfully study to promote the material interests of the community lies in the middle region between fundamental and practical research.

The idea of the duty of watchfulness against State encroachments or enticements proved to be the keynote of most of the discussion which followed Lord Balfour's address. Prof. E. R. Holme, of the University of Sydney, while proudly asserting that in Australia there has never been a sustained public policy that is contrary to the right British tradition, admitted the existence of dangers in the large "and necessary" dependence upon the State which characterises Australian universities. A specially insidious risk is that of political parties being tempted to make capital out of the pride of the people in their university and the desire to spread its benefits—to make, in American parlance, the campus of the university coterminous with the State.

This same danger was touched upon in a paper by President Klinck, of the University of British Columbia, one of the four State (Provincial) universities of Western Canada—who remarked, however, that while the unwillingness of the universities to pander to the expectations of those primarily interested in utilitarian education has led to their disappointment and disillusionment, it has not yet led to any appreciable diminution in the numbers demanding admittance. He was able to assure the Congress that the governors of a State university in Canada are no more liable to be dictated to by the legislature than the governing board of an endowed institution by private benefactors. The academic freedom of the professorial staff in the State universities is even more jealously guarded and more universally respected than is freedom from political interference in matters affecting the financial administration of the universities. The legislatures are not interested in staff appointments or in the details of academic policies, but leave the universities completely autonomous in these respects.

Prof. Holme referred to a recent political agitation of the question of the Australian universities' duty to country students, and, in this connexion, to the commission now studying the project of a Commonwealth University at Canberra for examinational purposes only. He suggested that the University of London might well offer to undertake for Australia the function of such a Commonwealth University. Either plan would have the advantage that Australian universities would not be driven to establishing (as Queensland has done) departments of "teaching by correspondence." Sir Theodore Morison suggested that the proper safeguard against the exertion of undue influence, whether by the State or by benefactors, is to present a bold front and a frank exposition of the grounds of the university's claim to autonomy. Prof. Payne, of Melbourne, quoted an instance of a government offering a chair coupled with the name of a prospective holder—an offer which the university rightly refused.

Sir Alfred Hopkinson summed up the relationship of State and university under five heads: Initiation, which should not be, and in the past has not been in Great Britain, the business of the State; recognition, which should always be in the hands of the State, to prevent fraudulent degree-granting; support, for which, ideally, the university should not be mainly dependent on the State; control, which should not be exercised by the State except to the extent of seeing that State grants are spent on development and not on fancy fads; service, in which there should be close co-operation. This last aspect of the relationship between State and university was presented with some enthusiasm in a speech by Dean Mackay, of the graduate school of McGill University, where, he said, the prevalent attitude towards the State is one, not of watchfulness against imaginary dangers of interference by the State, but of eagerness to promote its welfare. In one respect this has been prejudicial to the university, for it has led to an excessive withdrawal of the most talented alumni for the service of the State in other spheres.

"Co-operation in Research throughout the Empire" was discussed at the morning session of July 14 under the presidency of Lord Londonderry, Chancellor of the Queen's University of Belfast. This session attracted a maximum attendance—between five and six hundred. Sir Thomas Holland outlined the history of the Department of Scientific and Industrial Research and the various other governmental agencies in different parts of the British Empire for promoting and conducting research—agencies which, originating in the necessities of the War, have demonstrated that they are equally indispensable in time of peace. Two questions in connexion with them were, he suggested, of obvious importance to the Congress: "Does the establishment of Government laboratories tend to supplant university functions?" and "Can the universities take further advantage of the new official machinery for correlation and financial support?" To the first the answer seems, he said, to be favourable so far as Britain is concerned, but such official institutions have a strong natural tendency to extend their activities. This tendency is minimised where, as in England, the scope of their work is strictly limited to well-defined, large-scale investigations beyond the capacity of any university to undertake, and the universities are well represented on controlling committees. As regards the second question, he had found at the Imperial College a ready response to suggestion and a willingness to render the necessary financial assistance to research workers.

Sir John Farmer, professor of botany at the Imperial College, suggested that more might be done towards keeping the universities in touch with scientific workers in the outlying parts of the British Empire. The universities might, for example, give assurances that such workers would be welcomed

should they visit the university laboratories when on leave in England. At present the universities seem, he said, scarcely alive to the importance of the great development that is going on in tropical agriculture, and the opportunities open to their graduates in connexion therewith. Dr. Andrew Balfour, of the London School of Hygiene and Tropical Medicine, complained of the ignorance on the part of men working in his field of what others working in the same field are doing. An organisation is badly needed for laying down lines of research, following up what is done, and deciding what results should be recorded and how. India has its Scientific Advisory Board, which advises on the disposal of the Indian Research Fund Association's money, but it has no link with England. A central co-ordinating body in London, possibly a committee of the Medical Research Council, should be established, and one of its most important functions should be the selection and training of personnel. A recent promising move in this direction is the appointment of a Chief Medical Advisor to the Colonial Office.

The same subject, co-operation in research, came up again for discussion on July 10 under the title "The Actual Working of the Ph.D. Scheme." Questions relating to facilities for the migration of university teachers and students were touched on in this discussion, and were dealt with at other meetings under various aspects: interchange; an Imperial policy in education; mutual recognition of examinations; pension schemes The sectional meeting devoted to the discussion of "An Imperial Policy in Education," under the presidency of Sir Frederick Lugard, aroused much interest A paper on the subject was read by Prof Earle, of the University of Hong-Kong, who advocated the formation of a committee with a constitution designed to secure interest in the assistance of educational effort throughout the British Empire, a function which the Universities' Bureau is not competent to undertake

University and Educational Intelligence.

BIRMINGHAM. Applications are invited for the Walter Myers travelling studentship for research in pathology, value 300*l*. for one year. Candidates must be under 30 years of age and graduates in medicine of the University of Birmingham or of some other university in Great Britain or Ireland. In the case of graduates of other universities, candidates must have been students of the Birmingham Medical School for three years immediately preceding their application for the studentship

Further information may be obtained from the Dean of the Medical Faculty, and applications must be lodged with the Dean not later than September 1 next.

CAMBRIDGE.—The late Captain H. E. Laver has bequeathed to the Museum of Archæology and Ethnology his collection "of Chinese and the Far East Archers' Implements, meaning all [his] collection of Bows and Arrows and all implements connected with the manufacture of the same and all [his] Archers Thumb Rings, consisting of Jade and other hard stones of Ivory, Bone, Porcelain, Glass and Metal." One of the conditions of the bequest is that the specimens shall never at any time be lent for exhibition out of the precincts of the University

C. R. N. Winn, Trinity College, has been nominated by the Vice-Chancellor to the Choate Memorial Fellowship at Harvard, and N. H France, St. John's College, to the Princeton Visiting Fellowship. The Harkness Scholarship for geology has been awarded to M. Black, Trinity College, and the Wiltshire Prize to F. W. Shotton, Sidney Sussex College.

The Observatory Syndicate reports the addition of a photo-electric photometer, mainly by Günther and Tezetmeyer, to the equipment of the Observatory. The photometer will be used with the Sheepshanks equatorial.

C. B. Timmis has been elected to the Caldwell Studentship at Corpus Christi College.

MANCHESTER.—The Council has made the following appointments: Mr. H. E. Buckley to be lecturer in crystallography; Miss Margaret S. Willis to be assistant lecturer in geography; Dr. C. E. Brunton to be demonstrator in human physiology; Dr. O. R. Howell, lecturer in applied chemistry in the faculty of technology; Mr. Robert Grindley, demonstrator in chemical technology in the faculty of technology.

THE Air Ministry has announced that five hundred aircraft apprentices, between the ages of 15 and 17 years, are required by the Royal Air Force for entry into the Schools of Technical Training, Halton, Bucks, and Flowerdown, near Winchester They will be enlisted as the result of an open and a limited competition held by the Civil Service Commissioners and the Air Ministry respectively Successful candidates will be required to complete a period of twelve years' regular Air Force service from the age of 18 years, in addition to the training period. Full information regarding the aircraft apprentice scheme, which offers a good opportunity to well-educated boys of obtaining a three-years' apprentice course of a high standard and of following an interesting technical career, can be obtained on application to the Secretary, Air Ministry, Kingsway, London, W C 2.

VACATION courses being held in Germany this summer are described in a 16-page pamphlet published by 'Hochschule und Ausland,' Charlottenburg. Courses for foreigners in the German language and culture are provided by, or in connexion with, the Universities of Berlin, Greifswald, Heidelberg, Jena, Kiel (of special interest to Swedish students), and Marburg. Göttingen (October 4–14) and Munich (September 27–October 9) offer post-graduate medical courses; the Nordic Association of Lübeck is giving (August 2–20) a course of lectures for foreigners entitled "German Light on European Problems" Greifswald has an attractive programme including not only literary, artistic, and philosophical subjects but also astronomical, botanical, chemical, geographical, geological, physical, and psychological. The Jena courses are grouped in ten divisions including philosophy, pedagogy, University extension problems, natural science, domestic science, political and economic science, and German for foreigners.

THE Board of Education announces that the Institution of Naval Architects and the Worshipful Company of Shipwrights have consented to co-operate with the Board in arrangements for the award of national certificates in naval architecture to students in technical schools and colleges in England and Wales. Under the agreement which has been reached, 'Ordinary Certificates' and 'Higher Certificates' will be issued jointly by the Institution and the Company and the Board on the successful completion of approved courses. The scheme will provide only for part-time students. Should the authorities of any school in England or Wales desire further information, their inquiries should be addressed to the clerk to the Worshipful Company of Shipwrights, 4 New London Street, London, E.C.3, in the case of ordinary certificates, and to the secretary of the National Certificates Committee, Institution of Naval Architects, 5 Adelphi Terrace, London, W.C.2, in the case of higher certificates.

Contemporary Birthdays.

July 25, 1848. The Earl of Balfour, K.G., O.M., F.R.S.
July 26, 1872. Prof. Joseph Barcroft, C.B.E., F.R.S.
July 27, 1857. Sir E. Wallis Budge, D.Litt. (Oxon.).
July 27, 1857. Dr. John William Evans, F.R.S.
July 28, 1843. Sir W. T. Thiselton-Dyer, K.C.M.G.
July 28, 1844. Sir Howard Grubb, F.R.S.

The EARL OF BALFOUR, Chancellor of the University of Cambridge, and also of the University of Edinburgh, was born in Scotland. He was educated at Eton and Trinity College, Cambridge. Always deeply interested in the advancement of science, he is a past-president of the British Association, and has, at two separate periods, served on the council of the Royal Society.

Prof. JOSEPH BARCROFT was educated at Bootham School, York, and King's College, Cambridge. He succeeded the late Prof. J. N Langley as professor of physiology in the University of Cambridge, and is also Fullerian professor of physiology in the Royal Institution. His researches on the respiratory function of the blood and its relation to the activity of the tissues form but one department of many physiological inquiries He has explored the conditions of life at high altitudes with persistency and acumen, undertaking the leadership of two expeditions for that purpose, one to Monte Rosa, and another to the High Andes. Prof. Barcroft was awarded a Royal medal by the Royal Society in 1922.

Sir WALLIS BUDGE, Oriental scholar, formerly keeper of Egyptian and Assyrian antiquities in the British Museum, is a graduate of Christ's College, Cambridge. He has conducted excavations at Assuan, Nineveh, in the Sudan, and elsewhere.

Dr. JOHN W. EVANS, lately president of the Geological Society of London, was educated at University College School. He has rendered much service to geological science by initiating, extending, and guiding the conduct of geological investigations in the colonies and dependencies of the British Empire. In western and southern India and in South America he has led official exploring expeditions The Geological Society recognised the high value of his work by awarding him, in 1922, its Murchison medal. Dr. Evans is the author of a useful pamphlet of 20 pp. issued by the Colonial Office in 1914, on "Directions for the Collection of Geological Specimens."

Sir W. T. THISELTON-DYER, who was born at Westminster, attended King's College School, graduating afterwards at Christ Church, Oxford. In 1875 he became assistant director of the Royal Botanic Gardens, Kew, and he was director from 1885 until 1905. The "Flora Capensis," recently completed, and the "Flora of Tropical Africa," which will run to eleven or twelve volumes, will always be associated with his many years at Kew, where he also started the *Kew Bulletin* He has contributed notably to the economic and systematic botany of the British Empire.

Sir HOWARD GRUBB, to whom our hearty congratulations are extended on the occasion of his eighty-second birthday, was educated privately and at Trinity College, Dublin The practical outcome of his skill and labours in the production of objectives and instruments of precision is known wherever there are observatories. Early this year Sir Howard was the recipient of a congratulatory address signed by the leading astronomers and astrophysicists of Great Britain, referring to his resourcefulness and ingenuity in the development of the instrumental equipment of astronomers through more than sixty years.

Societies and Academies.

LONDON.

Optical Society, June 24.—M. von **Rohr**: Joseph Fraunhofer and the development of optical instruments. The position of high-grade optical work at the beginning of the nineteenth century was discussed. The chief cause of the transference from England to Germany of supremacy in telescope construction at that time was the appreciation in the latter country of the importance of fundamental research to the industry. The developments which took place in Munich and later at Benediktbeurn due to Fraunhofer's activities were detailed and some of the more important instruments produced under his direction were described.—T. **Smith**: (1) Reflection as a special case of refraction. Some difficulties which arise in applying the formulæ for refraction to reflection, and particularly the sign conventions which should be adopted for reflection, were discussed. (2) On the light transmitted and reflected by a pile of plates. The properties of a series of media or of a pile of plates which absorb and scatter light, and the interfaces of which may also absorb and scatter as well as transmit and reflect light, were investigated. In general, the ratio of the transmissive factors of a pile of plates in the two directions is independent of all reflective properties of the surfaces, and the factors are equal if the individual transmissive and absorptive factors are the same for the two beams. The ratios of the light transmitted without reflection to the total light transmitted are equal in both directions. The reflective properties of the pile depend upon all the factors of the system, and the ratio of the two reflective factors is not independent of the order in which the plates are placed. In non-absorbing systems, the sum of the intensities of the reflected and transmitted beams is equal to the intensity of the incident beam, and the ratio of the intensity of the reflected to that of the transmitted beam is equal to the sum of the corresponding ratios for the component plates or surfaces of the pile. Such a pile forms an exception to the rule that the reflective coefficients depend on the order in which the plates are arranged.—D. S. **Perfect**: Note on the immutability of transmissive factors with reversal of light. Direct experimental evidence has been obtained that the transmissive factor of the surface separating two media is unaltered if the direction in which the light travels is reversed.

DUBLIN.

Royal Dublin Society, June 22.—P. A. **Murphy**: The downy mildew of onions (*Peronospora Schleideni*), with particular reference to the hibernation of the parasite.—W. R. G. **Atkins** and H. H. **Poole**: Photo-electric measurements of illumination in relation to plant distribution (Part 1). Measurements of the illumination in shaded and open sites have been made by means of two photo-electric photometers and an apparatus already described, the readings being nearly simultaneous. The ratio of the illumination at a shaded site to the illumination due to diffused light in the open forms a useful index for comparing different sites. This ratio is conveniently expressed as a percentage which is called the daylight factor. It is usually found with both the photometers horizontal (so as to measure the vertical illumination), but a useful value near the edge of a wood is that found by tilting the photometer so as to receive the maximum illumination. There is a marked correlation between the flora and the daylight factors of the sites examined.—J. **Reilly** and G. T. **Pyne**: Studies in peat (Part 1). The thermal decomposition of peat under reduced pressure. Distillations of dried peat

were carried out under atmospheric and reduced pressures, and at both low and moderately high temperatures. The vacuum distillations gave larger yields of tar, of the heavier acidic substances, and of paraffin, while those at atmospheric pressure gave larger yields of simpler products such as ammonia, methyl alcohol, acetic acid, and gases. This points to a type of decomposition under low pressure favouring the formation of the more complex intermediate products.—J. **Reilly** and Miss H. E. **Bastible**: The velocity of formation of 3-5-dimethylpyrazole-4-diazonium chloride. The rate of reaction between nitrous acid and the amine was retarded by working in $N/100,000$ solutions. Owing to the great stability of 3-5-dimethylpyrazole-diazonium salts, measurements were possible up to comparatively high temperatures. The reaction is bimolecular, and at 0° C., $K=0.022$, the value increasing regularly with rise of temperature. At 72° C., $K=5.8$, more than 90 per cent. of the nitrous acid being destroyed in two minutes. In a control experiment without the base, less than 1 per cent. of the acid was destroyed in two minutes at 100° C.

PARIS.

Academy of Sciences, June 14.—E. **Goursat**: A problem of the theory of surfaces.—Marcel **Brillouin**: The centre of gravity and moments of inertia of the oceans. The mean action of the earth on the ocean.—Charles **Moureu**, Charles **Dufraisse**, and Paul Marshall **Dean**: A coloured hydrocarbon: rubrene. The substituted phenylacetylene, $(C_6H_5)_2CCl.C:C.C_6H_5$, has been proved to be very unstable, owing to the mobility of the atom of chlorine. If this compound is heated alone in a vacuum, hydrogen chloride is evolved, and from the residue a new hydrocarbon (rubrene) can be extracted, distinguished by its fine orange red colour, high melting point (331° C.), and sparing solubility in ordinary solvents. It combines with four atoms of bromine giving derivatives remarkable for their stability at high temperatures, one melting at 460° C. and another at 500° C., both without decomposition.—A. **Blondel** and A. **Dargenton**: Apparent brilliance of the face of exit of an optical system with any number of thick lenses.—Léon **Guillet**: The cementation of copper and its alloys by aluminium. As cementing agent an aluminium copper alloy (aluminium 20 per cent.) was used, the powdered alloy being mixed with 5 per cent. of ammonium chloride. Details of the results of experiments with various alloys are given, including the depth of penetration, hardness of the surface, and microscopic structure of the surface.—Charles **Nicolle** and Charles **Anderson**: Recurrent fever transmitted both by Ornithodorus and by lice. Sadi de Buen has recently announced the existence in Spain of a special type of recurrent fever, not transmitted by lice, but by *Ornithodorus marocanus*. These experiments were made on rats, but the author now proves that if monkeys are substituted for rats, the Spanish recurrent fever can be transmitted both by lice and by Ornithodorus.—N. E. **Nörlund** was elected corresponding member for the Section of Geometry in succession to the late Cl. Guichard.—Bertrand **Gambier**: Voss-Guichard surfaces.—Gaston **Julia**: Correction to the note on the polynomials of Tchebichef. Admitting priority to D. Jackson and G. Polya.—E. **Lainé**: Equations of the form $s=f(x, y, z, p, q)$ which are of the first class.—Jacques **Risler**: The formation of luminescent helium tubes. Details of the methods of purifying the helium and cleaning the tubes from foreign gases.—D. K. **Yovanovitch** and Mlle. A. **Dorabialska**: A new method for measuring the absorption of the β- and γ-radiation of radioactive bodies. The usual method consists in measuring the ionisation produced by the energy remaining in the rays after traversing several layers of material: the method now proposed is to measure calorimetrically the energy retained by the material itself in the form of heat.—**Frilley**: Absorption of the penetrating radiation of actinium in equilibrium with its derivatives.—René **Dubrisay**: Researches on surface actions. Solutions of various dyes (methylene blue, congo red, methyl orange, etc.) were shaken with absorbent materials (sand, kieselguhr, asbestos, cotton) and the quantity of dye adsorbed measured colorimetrically. The addition of an electrolyte, sodium chloride, increased the amount adsorbed in every case.—P. **Mondain-Monval**: The thermal properties of the various varieties of selenium. The heat of transformation of vitreous selenium into metallic selenium at 130° C. was found to be 13·5 cal. per gm., and that of red crystallised selenium at 150° C. into metallic selenium, 2·2 cal. per gm.—A. **Kirrmann** and H. **Volkringer**: The absorption in the ultra-violet of two isomers. The substances compared were the two bromoheptenes, $C_5H_{11}-CH=CHBr$ and $C_5H_{11}-CBr=CH_2$.—L. **Barthe** and E. **Dufilho**: The estimation of sodium: applications. A modification of the method of Blanchetière suitable for material containing organic matter or phosphates. The sodium is precipitated as the triple acetate of uranium, magnesium, and sodium.—B. **Bogitch**: The removal of iron from copper and nickel matte.—Charles **Prévost**: The two stereoisomeric α-ethylene-γ-glycols.—P. **Russo**: The presence of three transported beds in the southern Rif.—Pierre **Termier**: Remarks on the preceding communication.—**Pouget** and **Chouchak**: The radioactivity and chemical composition of the mineral waters of Hammam des Ouled Ali.—Ignace **Puig**: The large electromagnetic disturbances of the four first months of 1926 according to the records of the Observatory of Ebro, Tortosa, Spain.—André **Dauphiné**: New experiments on the vascular relations between the leaf and the root.—B. P. G. **Hochreutiner**: A new genus, intermediate between the Malvaceæ, the Bombacaceæ and the Sterculiaceæ.—L. **Blaringhem**: The production of double flowers as a result of complex crossings between divergent species of Geums (Rosaceæ).—G. **Mouriquand**, M. **Bernheim**, and Mlle. **Theobalt**: The antirachitic power of Wood's light. The radiations corresponding to Wood's light possess a protective action against the development of experimental rickets.—R. **Legendre**: The presence of two sea birds in the stomach of *Lophius piscatorius*.—R. **Courrier**: The quantitative action of the follicular hormone.—Em. **Perrot** and M. **Rouhier**: *Yocco*, a new drug containing caffeine. The bark of the stem of a plant known as Yocco grown in Colombia, especially in the Putumayo and Caqueta regions, is used as a stimulant by the natives. The bark contains about 2·7 per cent. of a crystalline substance presenting all the characters and reactions of caffeine.

ROME.

Royal Academy of the Lincei, May 16.—O. M. **Corbino**: Perot and Fabry fringes obtained with a half-silvered doubly refracting plate.—Federico **Sacco**: The tunnel at Drink (Valle d' Aosta). A representation is given of the stratigraphic metamorphic crystalline series traversed by the tunnel at Drink.—Angelo **Tonolo**: Equations for the conformable representability of a three-dimensional variety of Euclidean space.—Alessandro **Terracini**: The geometrical signification of the projective normal.—G. **Horn-D' Arturo**: The theory of flying shadows. The recent suggestions of Armellini and Ronchi with regard to the origin of flying shadows during solar eclipse are refuted, the author re-asserting his view that the light

intervals of these shadows represent real images of the solar crescent.—Giorgio **Abetti**: The structure of the *Hα* line of the chromosphere.—Filippo **Burzio**: Some new properties of ballistic precession.—E. **Persico**: Magnetic rotatory polarisation in an alternating field.—Ubaldo **Barbieri**: Astronomical determination of latitude and azimuth made at Cape Noli in 1911.—Ramiro **Fabiani**: First results of new investigations in the Permian outcrops in the Sosio basin (Palermo).—Enoch **Peserico**: The manner in which the electrical conductivity of the submaxillary gland is modified during its functional activity (ii.).—Giulio **Savastano**: Non-productivity of the pistachio in Sicily. Faulty fertilisation due to lack of pollen, rather than adverse climatic conditions or ovular abortion, is the principal cause of non-productivity.—P. **Pasquini**: Ineffective closing of the blastopore and subsequent development of the segmented ovum of *Rana esculenta* subjected to rapid centrifugation.—Constantino **Gorino**: The microflora of the Italian silo.

WASHINGTON, D.C.

National Academy of Sciences (Proc. Vol. 12, No. 5, May).—L. H. **Adams** and R. E. **Gibson**: The compressibilities of dunite and of basalt glass and their bearing on the composition of the earth. Direct measurements were made of the cubic compressibilities in the pressure range 2000 to 12,000 megabars (1 megabar = 1·0197 kgm./cm.^{2} = 0·987 atmos.). Assuming change of compressibility with pressure is a function of the compressibility, the compressibilities of dunite are $0·84 \times 10^{-6}$ and $0·79 \times 10^{-6}$ reciprocal megabars at 2000 and 10,000 megabars pressure respectively. The velocities of longitudinal waves at these pressures would be 7·9 km./sec. and 8·2 km./sec. Seismological data indicate that the velocity for longitudinal waves at 60 km. depth increases suddenly from 5·9 km./sec. to about 8 km./sec. The average compressibility of basalt glass was $1·45 \times 10^{-6}$ for the above pressure range, giving a velocity for longitudinal waves of 6·45 km./sec. The results suggest the existence below 60 km. of ultra-basic rock.—Edwin B. **Frost**, Storrs B. **Barrett** and Otto **Struve**. Radial velocities of 368 helium stars. Of these stars, 158 are spectroscopic binaries the periods of revolution of which are mostly only a few days. Using 350 stars, those brighter than mag. 2 have an average residual velocity of 6 km./sec., while for those fainter than mag. 5·3 it is 12 km./sec. The remainder have intermediate velocities.—George E. **Hale**: Visual observations of the solar atmosphere. The spectrohelioscope is of value for detecting exceptional phenomena quickly, while observations can readily be made with light of different wave-lengths. The chromosphere, prominences, spots, and faculæ can be investigated, and the instrument affords a means of searching for solar magnetic and electric phenomena. In the laboratory it should prove of service in the study of arcs, sparks, and other light sources with lines of various types.—William C. **Bray** and Hal D. **Draper**. Capillary condensation and adsorption. Sorption isotherms have been found for water vapour on partially hydrated oxides of copper and manganese, and mixtures of them in the form of porous granules. There is a rapid increase of sorption at higher pressures due to condensation of liquid in the capillaries. This occurs only when the surface, covered with a monomolecular layer by adsorption, is sufficiently curved.—Cecil D. **Murray**: The physiological principle of minimum work. (ii.) Oxygen exchange in the capillaries. The principle of minimum work can be applied to the circulation in the arterial system and in the capillaries. The general conclusion is that a minimum principle holds in physiology; the internal environment is in a state of mobile equilibrium, its components settling down to a new equilibrium with new constraints.—Cesar **Uribe**: Nuclear division in the trophozoites of *Endamœba histolytica*. Stained preparations were made of the intestine of a cat experimentally infected. A consecutive series of stages of nuclear division in trophozoites is described. Cloudy material forming two polar masses and an "axial band" in which the spindle is embedded appear to arise from the karyosome. The polar masses are surmounted by two clear cones with a centriole at the apex of each. The number of daughter chromosomes is estimated as six.—D. L. **Hopkins**: The effect of hydrogen-ion concentration on locomotion and other life-processes in *Amœba proteus*. Optimum conditions for growth and reproduction of Amœbæ from both acid and alkaline solutions occur at about pH 6·7 and pH 7·6. Locomotion, measured by sketching a pseudopodium with a camera lucida at minute intervals, shows similar optimum points. A neutral solution seems to cause a marked change in permeability, leading to decreased movement and vitality.—A. F. **Blakeslee** and J. L. **Cartledge**: Pollen abortion in chromosomal types of Datura. The size and condition of the pollen is an indication of the chromosomal group to which a plant belongs.—Edward **Condon**. Remarks on penetrating radiation. (*a*) Assuming that an electron is a sphere of negative electricity of uniform density and that a proton is a point charge, it is calculated that the 'neutron' can execute simple harmonic motion with a frequency of the same order as that of Millikan's penetrating radiation. (*b*) Using a corrected absorption law to accord with the geometrical conditions of Millikan's experiment, the results suggest that the radiation observed is truly homogeneous. There are difficulties in accepting the 'neutron' postulated.—Edwin H. **Hall**. New evidence in favour of a dual theory of metallic conduction. This theory gives an explanation of the Peltier development of heat observed by Bridgman, where an electric current changes direction within a metal crystal.—R. de L. **Kronig**. (1) The magnetic moment of the electron. (See NATURE, April 17, p. 550.) (2) A theorem of space quantisation.—E. O. **Salant**: On the heat capacity of non-polar solid compounds. Taking Born's theory of the heat capacities of crystalline solids and assuming a mean vibration in all directions for the molecule, terms are obtained expressing the contributions to heat capacity by (*a*) molecular vibrations, (*b*) bond frequencies (determined by characteristic bond frequencies in the infra-red), and (*c*) vibrations of the atoms across their bonds.—Robert S. **Mulliken**: Systematic relations between electronic structure and band-spectrum structure in diatomic molecules (iii.). Molecule formation and molecular structure.—Richard C. **Tolman** and Sinclair **Smith**: On the nature of light. G. N. Lewis has suggested that an atom never emits a quantum of radiation except to another atom, the possibility of transmission being determined by the laws of interference. His crucial experiment of arranging a mirror on a pivot in order to detect the effect of reflexion of quanta from one half only, those from the other half being forbidden by interference laws, is considered inadequate. The suggestion is made that a radiation field contains both waves and light quanta, the latter carrying energy and the former providing a signalling system. When and where both wave and quantum theory permit, the action of light occurs.—Einar **Hille**: On Laguerre's series (iii.).—Tracy Yerkes **Thomas**: On conformal geometry.—R. L. **Moore**: Concerning indecomposable continua and continua which contain no subsets that separate the plane.

The Practice of Forestry in the British Empire.

THE practice of forestry as a science has been a plant of slow growth in the British Empire. Many reasons have contributed to this cause, the chief being the facility with which we have been able to obtain our requirements, either by imports from closely adjacent forests belonging to our Continental neighbours, as in Great Britain, or from the existing primeval forests, as in India and the great Dominions and Colonies. Forestry as a science on a par with agriculture has long been known and practised in many of the great European States. A study of the methods employed and the comparative ease with which forest property, both belonging to the States and to private proprietors, is managed and protected, will show that not only the people on the countryside, but also even the dwellers in the towns, and the great industrial classes, understand the value of forest property and to some extent the aims of a forest policy—that, in effect, the forest, in the economy of the countryside, has an equal value with the tracts devoted to agriculture.

Many motorists from Great Britain annually make the journey from the north to the south of France and pass through great tracts of forest, either in State or private ownership and managed with an efficiency which has long been unknown, or at least unpractised, in Britain. They will have remarked upon the absence of fences. Boundary ditches there may be, or hedges, but little in the nature of the artificially constructed fences so necessary at present in Great Britain if the forest areas are to be safeguarded from a public to whom their economic value to the nation at large is unknown, and from that pest the rabbit. During the War thousands of men and women from the British Empire must have seen some of the forests of France, but very few possessed even the little knowledge of forestry practice which would have enabled them to recognise the differences which underlie the management in France and in Britain; or to have appreciated one of the most essential necessities for the successful practice of forestry in a country—that the public should be so far educated as to understand its true value to themselves and therefore to respect and help in the protection of forest areas.

It is unfortunately a not uncommonly accepted idea in Great Britain that a proper conservation of forest tracts means entire closure and the prohibition of picnic parties, and so forth; or that the introduction of rational management into such areas of forest as have come down to us from early times in the form of Crown forests, *e.g.* the Forest of Dean, New Forest, etc., entails their destruction as beauty spots or what are

termed ' playgrounds ' for the public. The controversy which recently took place in the press in connexion with certain beautiful spots in the New Forest—old decrepit woods of admittedly great beauty and picturesqueness—is a case in point. It has had its counterpart in the past in the case of other beauty spots in Great Britain, and even outside Great Britain in other parts of the Empire. The enunciation of such opinions, often by men whose names carry weight with public opinion, incontestably proves that what may be termed a forestry ' sense ' is at present lacking in the British public and, it may be added, in the Empire public, if we except perhaps India. The growth of this forestry ' sense ' can only arrive with the young generations and through the schools; it is an asset for the future that some schools in Great Britain and the Empire are introducing the teaching of the elements of forestry and its potential value into their curricula.

The love, which is strong in the British, for the maintenance of beauty spots and old woods, is a perfectly natural one and an attribute which any race may be proud to possess. Where trees and woods, however, are in question, it will be conceded that, unlike old historic buildings and famous ruins, no Government department, such as that for the protection of Ancient Monuments, with which the late Lord Curzon was so closely identified, both in India and Great Britain, can maintain them in perpetuity. Each succeeding generation which clamours to maintain untouched, for example, the afore-mentioned old woods in the New Forest, is merely assuring the disappearance from England at no distant date (though they themselves may not live to see it) of one or more famous beauty spots. Yet, as the Continent of Europe well shows, to those possessing the education and knowledge to be able to see and appreciate the management of such problems, it is quite possible to put in practice a method of management which, whilst assuring the minimum of change in artistic values, for forestry and the cult of trees is a lengthy business, will preserve for future generations what the present ones are enjoying.

This is but one aspect of the practice of forestry science, far removed from the commercial aspect, but one in which, owing to the interest aroused, it is of the first importance that the present generations should endeavour to make themselves acquainted with—if only in the interests of their future posterity and the maintenance of many beautiful spots and regions in Great Britain.

That the introduction of and practice of scientific forestry within the Empire has come to stay appears assured from the fact that the Prince of Wales is setting an example to the country by his personal interest in the subject. As president of the Empire Forestry Association, he delivered an address at the annual meeting in March last. As would be expected from the Prince of Wales, he dealt with the matter from the Empire point of view. He alluded to the ten-years planting programme of 150,000 acres undertaken by the Forestry Commission in Great Britain, which it was hoped to complete within the next three years; he then discussed the present position of forestry in South Africa and the planting schemes being carried out in that country to provide its population with "the conifers which Nature has denied them," and the work upon which Canada, Australia, and New Zealand are engaged.

Perhaps as great and, in some cases, greater advances have been made in the many forestry services, some already of considerable age, under the Colonial Office in the Malay States, Nigeria, Gold Coast, Kenya and the other East African colonies, and elsewhere. But the greatest of all, in point of progress, is the case of India. The first scientific forest service inaugurated in the British Empire was commenced in that country more than sixty years ago. A paper dealing with the practice of forestry read in the north of Great Britain a short time ago commenced with the sentence, "Forestry is a new industry which is happily growing up within the Empire, and nowhere more rapidly than at home." In the past, and at the present day, the Empire has often been accused of working in watertight compartments, and the practice of forestry is no exception to the rule. India is the only country within the Empire at the present day in which it can be said that forestry as a science, occupying its place in the economy of the countryside and in the true interests of the people as a whole, has become recognised and appreciated alike by the statesman, the cultivator, and to a considerable extent by the more educated of the public outside the great towns. The *Journal of the Empire Forestry Association*, to the value of which the Prince of Wales alluded in his address, has clearly exhibited to the trained forest officer the position which forestry science and practice has attained in India—a position which in some parts of the country vies with the best to be seen on the Continent of Europe. A study of the lines of management and work in the Indian forests and the research work which has been carried out, especially in connexion with the utilisation of tropical timbers, will be as useful to many of our Empire forest officers as the studies they have made in Europe.

It would not be in the true interests of forestry in Great Britain to say that, within the short space of time which has elapsed since the Forestry Bill was passed by Parliament some seven years ago, the industry—or, to give it its true name, since the industrial is but one side

of the business—the science of forestry has as yet made great strides. A beginning has been made, but forestry cannot hope to take its real place in the economy of the nation or of the Empire as a whole until the public has become educated and has accepted its aims and objects, alike from the economic and amenity points of view.

E. P. STEBBING.

Science and Psychical Research.

The History of Spiritualism. By Sir Arthur Conan Doyle. In 2 vols. Vol. 1. Pp. xiii + 342 + 8 plates. Vol. 2. Pp. vii + 342 + 8 plates. (London, New York, Toronto and Melbourne: Cassell and Co., Ltd., 1926.) 42*s*. net.

THE recent publication of two large volumes entitled "The History of Spiritualism" by Sir Arthur Conan Doyle is perhaps a suitable occasion on which men of science may once again turn their thoughts in a direction in which many more of them are probably interested than would be willing to admit it. Spiritualism is a cult, a faith, or perhaps even a full-blown religion, the central tenet of which is sufficiently well stated by Sir Arthur (vol. 2, p. 263) in the following words:

"A belief in the existence and life of the spirit apart from and independent of the material organism, and in the reality and value of intelligent intercourse between spirits embodied and spirits discarnate."

Spiritualism as a religion does not come within the confines of the subjects which a scientific periodical like NATURE may appropriately discuss. But right through the warp of Sir Arthur's book, though by no means carefully distinguished, and most certainly very unscientifically handled, runs the woof of psychical research, which is, or at any rate purports to be, the *scientific* study of what are called *supernormal phenomena*. These phenomena are of two kinds—(*a*) *physical*, such as telekinesis, or movement of solid objects without contact; independent voice, or the production of sound recognisable as that of the human voice and recordable objectively on a dictaphone; the formation of the substance known as ectoplasm or teleplasm; psychic lights and cold breezes; formation of structures invisible except by the reflection of ultra-violet rays; and so on: (*b*) *mental*, such as clairvoyance, clairaudience, automatic script, telepathy and other similar types of phenomena not involving the use of material objects.

Many years ago, when this question of psychical research was brought to his notice, Huxley replied, "Supposing these phenomena to be genuine, they do not interest me." We are sorry to be obliged to have to record so unscientific a remark from so great a man, and even sorrier to have to admit that Huxley's attitude is still that of the great majority of biologists at the present day. The opinion of any man, however great, or of any body of men, however influential, on a subject which they deliberately refuse to investigate, either because it "does not interest" them, or because of a preconceived idea that the phenomena involved are necessarily fraudulent, is really not worth much. It is a sad commentary on human nature that, even at the present day, when the reality of some at least of these phenomena has surely been put beyond the shadow of a doubt by the work of such men as Lodge and Richet, no scientific man can take up the study of psychical research without 'losing caste' and undergoing either secret or more or less open persecution from his fellows. Truly, we have not got very far from the Middle Ages after all, and there is a very real danger that organised science in the twentieth century is taking its seat in the very chair from which it once drove the medieval church. "E pur si muove" applies equally to the movement of the earth round the sun or to the movement of a levitated table upwards against gravity without visible support. The former was no more incomprehensible and no less anathema to the medieval church than the latter is to-day to organised science. But the spirit of to-day is different from that of the past, and martyrdom no longer wins many converts. Modern Galileos may undergo persecution for what they hold to be the truth, but the modern world will soon forget them in the hurry and rush of modern life, and the truths for which they suffer will perish with them unless they can be presented in such a form as to appeal to the reason of mankind.

It is just here that a great danger lies. The history of the world is full of evolutionary failures; for every organism, Nature selects a path from which there is no turning back. The advance of science during the past seventy years has been definitely along the road to materialism. Though the pace has somewhat slackened and many an anxious glance is now being turned backwards, yet the impetus is still driving us forward mainly in the same direction. For hundreds of years mankind looked to religion to lead them along the right path. Now, in the western world, their gaze is fixed on science. It is certain that, for the next hundred years at any rate, where science leads, there mankind will follow. Are we, the men of science, the leaders of mankind, so absolutely sure of the path along which we are travelling?

Pilate's question "What is Truth?" has never yet been answered, and perhaps it never will be. It is, however, the duty of science to search diligently for truth and to leave no avenue unexplored in which it may be found. The broad highway may lead us to

destruction, even if it appears well marked out and easy to travel upon. The neglected side-path, foul with mire and overgrown with noxious weeds, may be the real entry into the Promised Land, for which we are searching. But because of the foul mire, and because of the noxious weeds, organised science refuses to explore this side-path, in spite of the fact that a few brave spirits, more adventurous than the rest, a Crookes, a Lodge, a Richet, have penetrated into the thicket and returned to report both progress and promise.

The present writer cannot claim the experience either of a Lodge or a Richet in the study of psychical research. His interest in the subject is one of comparatively recent growth and arises chiefly from dissatisfaction with the adequacy of present-day biological theories to explain life in acceptable terms. He can, however, claim sufficient experience to be able to say, with both Lodge and Richet, that a clear case has been made out for psychical research, and that it is the duty of science to recognise the genuineness of the phenomena and to attempt to explore them. Fraud exists, and always has existed, in all branches of human affairs. It is even blatantly active in biology, to judge by the remarks passed quite recently by leading British and American biologists on the work and character of a certain Austrian professor. Let fraud and cheating be exposed, certainly, wherever it exists; but is that any reason for refusing to accept as a recognisable branch of science any subject in which fraud has been found?

It appears to the writer that the best avenue of approach for men of science to make on this subject is the study of the so-called physical phenomena. Either these are entirely fraudulent (that is, due to conscious or subconscious cheating on the part of the medium), or else they extend the realm of physics beyond the boundaries explored at present. Take, for example, one of the simplest and most easily experienced of the physical phenomena, that of *cold breezes*, which generally precede any manifestation of greater energy in a séance. It has been maintained that this effect is purely subjective, that the sitters imagine they feel the cold owing to the tense situation created in the mental atmosphere of the séance room. In the National Laboratory of Psychical Research, two very accurate thermographs have recently been installed. One of these is placed against the wall of the room, far from the sitters, while the other records the changes which occur in the temperature of the closed cage of the Pugh table in which phenomena occur during sittings with the medium Stella C. in red light.

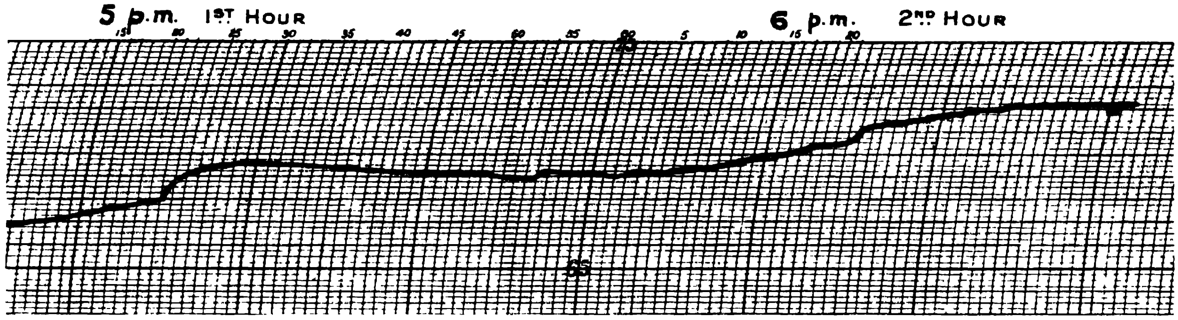

FIG. 1.—Thermograph record inside Pugh table. Temperature at 5.10 P.M., before beginning of séance, 67° F. Red light throughout.

5.23 P.M. Stella goes into trance. Marked rise in temp.
5.30 to 5.55 P.M. Steady fall in temp.
5.55 P.M. Electric bell with contact inside closed cage was rung vigorously four times within a minute or two. Note irregularity in thermograph record.
6.24 P.M. Bright light flashed inside cabinet.
6.29 P.M. Zither pushed partly out of opening in Pugh table.
6.33 P.M. Two very fine blue flashes inside Pugh table.
6.42 P.M. Stella comes out of trance.

Note.—Cold breezes preceded each of these phenomena. Other phenomena were also recorded at 5.30, 5.42, 5.48, 5.51, 5.58, 6.01, 6.05, 6.07, 6.[illegible], 6.16, and 6.18 without any sudden variation of thermograph record.

The control thermograph record taken separately on the wall of séance room, about 10 feet from the medium sh[illegible] a steady rise in temperature without any marked changes in gradation from 67° F. at 5.10 P.M. up to 69.5° F. at end of séance.

Normally, when a number of people sit in a closed room, the temperature mounts steadily upwards; this is also the case for the temperature of the séance room as recorded on the wall during a sitting. But the record of the temperature inside the Pugh table shows a steady rise at first, followed by a fall during the production of supernormal phenomena, as in the accompanying record (Fig. 1); there are also several marked sudden changes at points where special phenomena occurred. These careful experiments prove the objective nature of the cold breezes and present us with a purely physical problem, which is surely worth solving. It is not an extravagant hypothesis which finds an explanation for the production of 'supernormal' physical phenomena in the withdrawal of heat from the circle of sitters, such heat being turned into some other form of energy, possibly of a kind not yet investigated officially by science!

The so-called 'physical' phenomena of mediumship

should be of interest to biologists as well as to physicists, because, if they are genuine, they offer an avenue towards the study of the control and manipulation of matter by mind which is at present unique in its character. The invisible operators who apparently control the more striking phenomena of mediumship claim that they are able to draw out from the organism of the medium 'psychic stuff,' by the moulding of which they can produce at will the phenomena of independent voice, levitation, materialisations of portions of their personalities, and so on. We who have seen these things done under conditions precluding deliberate fraud are not fools, but in full possession of keen faculties. Every man who witnesses these phenomena and becomes convinced of their reality has only two choices before him. He can, as numbers have done, keep quiet and say nothing about it, thereby preserving the respect of his fellow-scientists and committing the sin against the Holy Ghost, namely, turning his back on truth when he has recognised it; or he can, like Sir Oliver Lodge, speak out the truth boldly and allow his reputation to drop in the estimate of his fellow-men. The writer ranges himself alongside Sir Oliver, well knowing what is in store for him in consequence. This article is a plea for a wider and more generous outlook on the part of science towards these phenomena. Science has nothing to fear from fraud; it need only go on applying its experimental method to any problem, and a solution will shape itself in time, either in the form of an overwhelming proof of the fraudulent production of the phenomena, or pointing towards the existence of genuine supernormal results.

The mind of man seems to have reached out so far in recent years that it has almost succeeded in exploring the entire limits of its own cage. Is it to rest in the belief that there is nothing at all outside that cage, or may it, so to speak, extend a cautious paw outside the bars and begin to feel its way towards a realisation that there may be another world outside? Psychical research may perhaps afford the only possible way of exploring the unknown territory outside the cage.

R. J. TILLYARD.

Civil Aviation in the United States.

Civil Aviation: a Report by the Joint Committee on Civil Aviation of the U.S. Department of Commerce and the American Engineering Council. Pp. xvii + 189. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1926.) 12*s*. 6*d*. net.

IN Europe rapid developments have been made in the application of aircraft to commercial uses. In the United States, however, air transportation, in spite of many conditions naturally favourable, has not achieved a development commensurate to the opportunities.

The Department of Commerce and the American Engineering Council, recognising this deficiency, have for some time past gathered information relating to this matter. A joint committee was formed in June 1925, to make a comprehensive survey of the economic aspects of aviation throughout the world, and to recommend the measures necessary to encourage a national development of commercial aviation in the United States. All available sources of information on this subject have been examined by the committee, including the attitude of American business interests and the experience of aircraft operators.

In the report before us, which here deals comprehensively with the situation, the committee lays down first and foremost the development of the commercial side of aircraft as of vital importance both to industry and to national defence. Whilst stressing the fact that development must mainly depend on private initiative and enterprise, the committee maintains that provision of facilities essential to this development is a public responsibility, and, if these facilities are provided, direct subsidies to civil aviation in the form of money grants are both unwise and unnecessary.

Certain fundamental difficulties, the committee maintains, are retarding the development of this venture in the United States. Broadly speaking, they are intimately associated with the lack of an established Government policy to encourage civil and industrial uses of aircraft; with the lack of commercial aircraft and equipment best adapted to commercial operation; and with the consequent want of public and business confidence and support.

After due consideration of the large part played by the commercial department and by big businesses in this field, the committee recommends a number of far-reaching proposals which, if adopted, would undoubtedly make a ground-work for a vast new development eminently suited to the geography of the United States. It is proposed that Congress should enact a civil aeronautic law providing for the establishment of a Bureau of Civil Aeronautics in the Department of Commerce; that is to say, it is to be completely dis-associated from the military or naval wing. It would be the function of this bureau, among other duties, to regulate civil air navigation, license pilots, and inspect machines; to develop, establish, and take over air routes and facilities, and generally to encourage and promote the aircraft industry on the civil side.

The committee, moreover, recommends that the several States should authorise their municipalities to acquire landing fields out of public funds and to lease them when necessary. Great stress is laid on the fact

 E 1

that the Government should not undertake any non-military flying activities, but that it should be left entirely within the scope of private operation. Even air mails, forest patrol, agricultural, entomological, and coastguard services, aerial photography, map making, etc., should be conducted by private agencies under contract wherever possible. Much assistance, however, is expected from the Government departments; the war, naval, and other departments are to permit the use of Government landing fields and to provide facilities for commercial operations. The Post Office should retire from the ownership and operation of air mail routes as soon as it is possible to contract with responsible private operators. The purchases of Government aircraft are to be arranged to conform to a definite and continuous programme which will give the greatest aid to the industry, and State encouragement is to be extended to the exportation of commercial aircraft.

Whilst much of the report is thus concerned with the part to be played by private owners, under security and assurance which is to be granted to those who are thus encouraged to invest their capital in the industry, scarcely any mention is made of that form of research and development which would be vital to maintain such an industry in the forefront of technical and scientific knowledge. There does occur a bald statement that the Government should carry on fundamental aeronautical research in the interests of civil aviation, but, unlike the other sections of the recommendations, this aspect does not appear to have been expanded, or its far-reaching implications grasped. From the point of view of the corresponding industry in Great Britain, it will be an interesting experience to watch how these proposals work themselves out in practice.

Military Explosives and Gases.

Explosifs, poudres, gaz de combat: leçons professées à la Faculté des Sciences de Lille. Par Paul Pascal. Pp. viii + 296. (Paris: J. Hermann, 1925.) 35 francs.

THIS book embodies the lectures delivered by Prof. Paul Pascal, of Lille, to candidates for the French Service des Poudres. While in Great Britain the Royal Naval College and the Artillery College afford specialised instruction to combatant officers in the subject matter of these lectures, in France this is also obligatory for chemical engineers destined for employment in the Government factories.

The first part of the book deals with the different aspects of explosive reactions, such as the temperature and pressure of explosion, its propagation on one hand by the explosive wave, and in the case of propellants by rapid burning, along lines which have been developed by the French masters in this subject, such as Berthelot, Vieille, Sarrau, and Le Chatelier.

The second and third parts deal with the manufacture of explosives, together with the properties of several of the more important ones. Naturally, in a book of this size, manufacturing details cannot be exhaustively given, and the treatment is sometimes unequal. At the same time, several of the processes used in Great Britain are accurately described, such as the displacement process for making nitroglycerine of Nathan, Thomson and Rintoul, and the displacement process for making nitrocellulose of the Thomsons.

The production of explosives derived from aromatic hydrocarbons was greatly hampered by France's loss of territory containing coke ovens, and acknowledgment is made of the assistance afforded by Great Britain in sending over benzol, the partition being roughly that while we kept the toluene to ourselves, France was supplied with the benzol from which were made phenol and its derivatives so largely used in French explosives during the War.

The occurrence of isomerides in the nitration of toluene is clearly described, as well as the large-scale methods for making trinitrotoluene. Thus attention is directed to the important features of the process developed in Great Britain, such as the detoluation of the waste acids and the process for continuous nitration of mononitrotoluene, a sketch of a nitrating vessel used here in the large factories being included. Mention is also made of the purification of the trinitrotoluene by alcohol and by sodium sulphite, although the principle of the latter process, which was developed first in France, is not described. As would be expected from the use of nitronaphthalenes in France for many years, their manufacture is fully illustrated, as is also that of synthetic phenol and its nitro derivatives, including a sketch of a continuous nitration process developed in this country for picric acid.

The manufacture of nitric peroxide and its use in aerial bombs, in which the fuel for this oxidising material was kept apart until the bomb was launched on its flight, are also described, this being a type of bomb that was used to some extent by the French when it was desired to have a very violent local effect.

Sections are devoted to the manufacture of gunpowder and also to the mixture of ammonium nitrate with the nitronaphthalenes, but little is said of the British Service high explosive amatol (ammonium nitrate and trinitrotoluene), the use of which it is understood the French were contemplating on a larger scale towards the end of the War.

Under smokeless propellants a description is given of the methods of manufacture of Poudre B, and the

French views are stated as to the stabilising action of amyl alcohol and diphenylamine. As a war measure these substances were sometimes omitted, and the nitrocellulose propellant was tinted red as a distinguishing mark. While the composition of British cordite MK. I. is correctly given, cordite M.D., which superseded it, is not mentioned; the composition, however, is given of cordite R.D.B. adopted by Great Britain for land service during the War, as it utilised the solvent ether-alcohol instead of acetone which was impossible to obtain in the quantities required. There is a short section on the preparation and properties of the initial detonants, mercury fulminate and lead azide.

The fourth part deals with gases used in warfare, and after a short statement as to their first employment and subsequent tactical use, proceeds to describe the different natures of 'gas,' lachrymatory, toxic and vesicant, sternutatory, etc., and the manufacture of various types. The longest description is given to mustard gas, for the making of which the different processes are compared; the French method of reacting on ethylene with a mixture of chlorides of sulphur approaching sulphur dichloride in average composition and dissolved in carbon tetrachloride is given in some detail.

Sections are also devoted to compounds of arsenic, their physical constants, such as density and vapour tension; in some cases figures are given illustrating methods of manufacture of these bodies.

This book should prove of interest to the technical expert, not only from the presentation of its subject matter, but also as it gives reasoned views sometimes at variance with those held in Great Britain. While the explosive subjects are treated in a manner suitable for the students to whom they are addressed, there would seem to be insufficient information on the properties of the explosives. Thus the book would have been more valuable if it had included some collected information giving the heat produced on detonation of the different types of explosives and their chemical stability, their sensitiveness, rates of detonation, and explosive effects.

Our Bookshelf.

Manual of the New Zealand Flora. By T. F. Cheeseman. Second edition, revised and enlarged by the Author. Edited by W. R. B. Oliver. Pp. xliv + 1163. (Wellington, N.Z.: W. A. G. Skinner, 1925.) n.p.

THE appearance of the long-expected second edition of Cheeseman's manual is most welcome, and, as the editor remarks, "the present edition of the manual will long remain the standard work on the flora." It is much to be regretted that Mr. Cheeseman died before the work was completed; but his full notes on the unfinished portions have enabled Mr. Oliver to complete the book according to Mr. Cheeseman's original ideas.

The value of the new edition is shown in the fact that 192 additional species, the greater number of which are new to science, are enumerated therein. In the family Compositæ alone 40 additions have been made, while in Scrophulariaceæ 25 new plants have been recorded, 19 of these being included in the genus Veronica. All but one of these latter belong to the very critical section Hebe (now considered a separate genus). A useful feature is Mr. Oliver's continuation of the history of botanical discovery in New Zealand, covering the years 1905–24, in which he gives references to the more important work done on the flora and cites broadly the places of publication. The list of Mr. Cheeseman's publications is an apt tribute to the writer of the manual, and at the same time valuable for purposes of reference. The lists of introduced species and native names have also been revised and enlarged and are of great value to the student. It is to be hoped that a fuller treatment of the former will not be long delayed.

In the body of the book the most notable feature is the replacement of Bentham and Hooker's system by that of Engler and Prantl in the arrangement of the families. Although this brings the manual into line with many modern floras, it is doubtful if such an alteration is advisable at the present time, when systems of classification are again under consideration. It is also rather a pity that the sub-kingdoms, classes, and sub-classes are not separated from one another adequately in the text, in accordance with the synoptical key given in the appendix.

In detail the arrangement of the text follows closely that of the first edition. One difficulty which is encountered in working with the manual in herbaria is the absence of collector's numbers in the enumeration after each species, but this, of course, does not arise in the field. Nevertheless, with the exception of a few minor mistakes, especially in the references, the general arrangement and finish of the book reach a high standard.

In spite of the many additions, the book has been kept within approximately the same compass by a slight enlargement of the pages, so that the whole volume is still easily handled.

Ticks: a Monograph of the Ixodoidea. By George H. F. Nuttall, C. Warburton and L. E. Robinson. Part 4: *The Genus Amblyomma.* By Dr. L. E. Robinson. Pp. xii + 302 + 8 plates. (Cambridge: At the University Press, 1926.) 20*s*. net.

THE genus Amblyomma is by far the richest in species of the genera of ticks, comprising many forms remarkable for the beauty of their ornamentation. Dr. L. E. Robinson considers the number of valid species to be eighty-six. Although not of such great importance as carriers of disease as some other genera—for example, the cattle ticks (Boophilus), also the genera Rhipicephalus and Dermacentor—the genus Amblyomma includes several forms very injurious to domestic animals. The South African 'Bont tick' (*Amblyomma hebræum*) is the principal transmitter of heartwater—

a disease frequently fatal to sheep, goats, and cattle. This tick and some allied species are known to cause very severe ulcerating sores, sometimes leading to the loss of one or more udders of the host. Pyæmia and other complaints of horses due to soil-infesting organisms are also believed to ensue from the bites of *Amblyomma variegatum* and allied forms. Live-stock infested with these ticks sometimes suffer greatly from loss of blood and 'tick worry' due to the large number of parasites present. The larvæ of *Amblyomma cajennense*—a common tick in the West Indies, Central and South America—are a great plague, freely attacking man and domestic animals.

Clear and concise descriptions of all the known species of Amblyomma are given in this work, and the illustrations are numerous and excellent. A few notes on biology are to be found at the end. Parthenogenesis is recorded as occurring in *Amblyomma dissimile* and *A. rotundatum*. The author is to be congratulated on producing a monograph which will certainly be of the greatest value to all scientific workers interested in the Ixodoidea, and will no doubt for many years remain the standard work on the genus Amblyomma.

A. S. H.

Die Kriegsschauplatze 1914–1918 geologisch dargestellt. In 13 Heften. Herausgegeben von Prof. Dr. J. Wilser. Heft 2 (zu Heft 1 gehörig): *Lothringen.* Von Prof. Dr. E. Kraus. Mit einem Beitrag (Abschnitt Jura) von Dr. W. Kluptel. Pp. viii + 212 + 4 Tafeln. 24 gold marks. Heft 3: *Zwischen Maas und Mosel.* Von Prof. R. Lais. Pp. iv + 116. 13·50 gold marks. Heft 13: *Sudostmazedonien und Kleinasien.* Von Prof. Dr. O. H. Erdmannsdoerffer, Prof. Dr. Cl. Lebling, Prof. Dr. K. Leuchs, Dr. K. Osswald, Dr. A. Wurm. Pp. v + 114 + 4 Tafeln. 18·60 gold marks. (Berlin: Gebrüder Borntraeger, 1925.)

THE conception of a series of volumes portraying the geology of the War areas as such has little to commend it either from the scientific or from any other point of view. Apparently numerous geologists were attached to the German Imperial staff to advise on such matters as water-supply, building materials, and the laying of mines; in the present volumes the results of their investigations are brought together.

Of the three now before us, the first two deal with areas of the western battle front, and give a fairly detailed account of the local stratigraphy and tectonics; there seems to be but little new matter, the contents being mainly a digest of information long ago published elsewhere. The volume on south-east Macedonia and Asia Minor consists of a series of articles recording the original observations of several geologists, who give most attention to tectonic structure; a few are accounts of hurried traverses, but a number of districts are surveyed in some detail.

The Effects of Inanition and Malnutrition upon Growth and Structure. By Prof. C. M. Jackson. Pp. xii + 616. (London: J. and A. Churchill, 1925.) 30*s.* net.

PROF. JACKSON'S book is a systematic review of the subject of inanition, which term he uses to indicate the lack of food or of any food-stuff which is essential to the living organism. The general outline is on a strictly anatomical basis, the effects of starvation and malnutrition being considered separately for each system of the body. There are also included chapters on the effects of inanition on plants, protozoa, and the higher invertebrates. The book is singularly complete. The author not only gives the results of his own researches into the subject, but reviews in the widest possible manner the literature of the last fifty years. He classifies the various states of inanition according to their character, degree, duration and severity, and mode of occurrence, and discusses fully the results of experimental starvation and the observations of morbid anatomists on cases of clinical malnutrition and deficiency diseases. Being a study from the morphological aspect, the book is of theoretical rather than practical interest to the physician, but it will be warmly welcomed by the pathologist and biologist. It is well indexed, and a very full bibliography is included.

The Works of Aristotle. Translated into English under the Editorship of Prof. W. D. Ross. *Categoriæ* and *De Interpretatione*, by E. M. Edghill; *Analytica Priora*, by A. J. Jenkinson; *Analytica Posteriora*, by G. R. G. Mure. Pp. 348. (Oxford: Clarendon Press; London: Oxford University Press, 1926.) Paper, 6*s.* net; cloth, 7*s.* 6*d.* net.

THE monumental work of the English translation of all the writings of Aristotle by the Oxford Aristotelian Society, under the editorship of Prof. W. D. Ross, has received its latest accession in this volume, which contains four of the logical treatises. They constitute the work of Aristotle which is usually placed at the beginning and about which there is the least difficulty and the smallest amount of controversy. More than anything else, more even than the "Metaphysic," they are responsible for the idea of 'authority' which attached itself to the name of Aristotle throughout the Middle Age. This edition makes it possible for the English reader to understand how the philosopher Immanuel Kant could cite logic as the example of a science which had emerged complete and perfect from its first formulation, and take it as the model of the work he himself proposed to do for metaphysics.

Physikalisch-chemische Mineralogie und Petrologie: die Fortschritte in den letzten zehn Jahren. Von Prof. Dr. Wilhelm Eitel. (Wissenschaftliche Forschungsberichte: Naturwissenschaftliche Reihe, Band 13.) Pp. viii + 174. (Dresden und Leipzig: Theodor Steinkopff, 1925.) 8 gold marks.

THIS is a welcome addition to the series of which it forms part. Within the limits of its scope, it is an invaluable guide to the results of recent investigations on the physics and chemistry of minerals and rocks. It is not intended to supersede larger works such as that of Boeke; but to constitute a supplement by which the student of the subject may bring his knowledge up-to-date. Similar publications are to follow on kindred subjects. It will be noticed that the author speaks of "Petrologie," not "Petrographie," as he is concerned with the evolution, not the mere discription, of rocks.

Letters to the Editor.

Spirals and Waves in Wool.

ALL the Merino wool imported from Australia and South Africa is characterised by a conspicuous waviness throughout the individual lock or staple (Fig. 1). When drawn out, each separate fibre exhibits a regular series of convexities and concavities, and it is the adjustment of these to one another which gives the waviness to the complete lock. They are permanent structural features, returning after the elastic fibre has been stretched. The degree of the waviness, whether close or open, shallow or deep, varies in individual fleeces, and affords a ready means by which the farmer and manufacturer estimate the fineness or

FIG. 1.—Staple of coarse Merino wool showing waves or crimp

coarseness of the wool, from which the 'spinning count' is largely determined.

Much discussion has taken place recently as to the manner of formation of this waviness, whether determined by unequal lateral growth of the fibre within the follicle or superimposed later by the mechanical conditions in the fleece. A comparison of the fine, compact, short Merino wool with the coarse, open, long wool of many of the British breeds is found to afford a satisfactory solution of the problem. In the first instance, examination has been made of the natal coat of a large series of Merino, Karakul, and British breeds of sheep, and these show a remarkable degree of similarity, despite the conspicuous differences which the adult fleeces display. In all instances the coat of lambs at, and shortly after, birth is constituted of short spiral tufts, curls or ringlets of wool, usually intermingled with larger, coarser, medullated fibres known as kemp, and representing the outer coat of primitive sheep (Fig. 2). The spirals reach their most regular and compact form in the natal coat of the Karakul, and it is this which gives the attractiveness of the so-called Astrakhan fur. They are well shown as close, distinct spirals in the Merino and Southdown, and as loose and more open in the curl in the coarse, straight wool of the Scotch blackface, but all intermediate stages can be obtained by comparing different breeds, or even from within a single breed. It is significant of the common origin of all the varieties

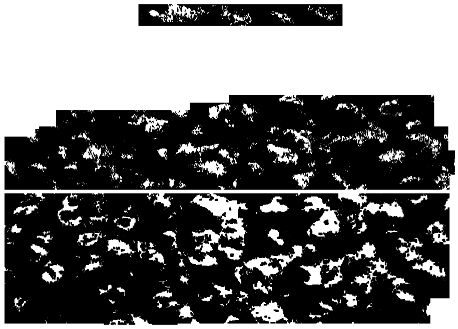

FIG. 2.—Natal fleece of Southdown with spiral tufts or ringlets under an outer coat of kemp fibres.

of sheep that at this early stage of their ontogeny their woolly coats should bear such a close resemblance.

Enclosed as the unborn lamb is within the fœtal membranes, and surrounded by the amniotic fluid, it is clear that the individual fibres, however close or scattered, can have little or no mechanical influence upon one another, and each one is free to assume the form impressed upon it by its structure. Therefore the spiral form they assume in the natal coat may be deemed to be that given them from their growth within the follicle, and to represent, as it were, the natural form of the fibre.

With the continuance of fibre growth after birth, new factors are introduced which modify the natural spiral form. If the staples are sufficiently free from one another as to be unimpeded in their growth, each

FIG. 3.—Staples of lamb's wool with spiral tufts (mother hair) at tip and wavy wool below.

continues the natal spiral form, and we get the well-known ringlets of the Leicester, Lincoln, and Wensleydale, as well as of the Angora goat. If, however, the fibres are so closely arranged that the staples press upon one another and form a compact fleece, then each lock is mechanically unable to assume the independent spiral form and the wavy structure is produced. The change can be best illustrated by compressing a rather open spiral of wire, the spire when flattened assuming a wave-like form, altogether resembling the waviness in the wool fibre. All

degrees of transformation of the spiral lock into the flattened wave can be traced in such fleeces as the Border Leicester, according as the staples are free throughout their length ('locky') or compact below for a greater or lesser part of their length.

The change from spiral to wave is also recognisable in the first coat of sheep having a short compact fleece, as in the Merino and Southdown. At birth, as already remarked, the coat consists of independent spirals, maybe with an outer coat of kemp. The spirals grow upwards as the tip of the corresponding lock or staple and retain their form, while the wool below is in waves or crimps (Fig 3). The spiral tips, known to the farmer as 'mother hair,' enable the woolman to determine wool of the first from later shearings.

The Reduction of Carbon Monoxide.

F. FISCHER (*Brennstoff Chem.*, 7, 97, 1926), in describing the formation at atmospheric pressure of solid, liquid and gaseous hydrocarbons by passing a mixture of carbon monoxide and hydrogen over a variety of catalysts, has advanced the theory that hydrocarbon formation depends on the transient formation of high carbon carbides which, by the action of hydrogen, give rise to products similar to petroleum. He states that no acids or other oxygenated substances are formed.

We have confirmed the formation of liquid hydrocarbons by passing an artificial water gas over a catalyst consisting of reduced manganese, cobalt and copper oxides (*Fuel*, 5, 263, 1926). Further experiments have shown the possibility of synthesising oxygenated compounds from this gas mixture, at ordinary pressure, although the literature available on the subject seems to indicate that pressure is essential for the production of such compounds. From thermodynamic considerations (Matignon), the reaction $CO + 2H_2 \rightarrow CH_3OH$ is scarcely possible at atmospheric pressure and $CO + H_2 \rightarrow HCHO$ cannot be carried out at all The following reactions are perhaps possible:

$$2CO + 4H_2 \rightarrow C_2H_5OH + H_2O$$
$$3CO + 5H_2 \rightarrow CH_3COCH_3 + 2H_2O.$$
$$2CO + 2H_2 \rightarrow CH_3COOH.$$

In an experiment where a gas mixture (composition 53·9 per cent. carbon monoxide and 41·6 per cent. hydrogen) was passed at atmospheric pressure over a contact mass consisting of the reduced oxides of manganese, cobalt and copper, impregnated with 0·5 per cent lithium carbonate at 302° C., we obtained evidence of the formation of products apparently similar to those obtained in the now well-known high-pressure reactions between these gases over certain catalysts

In this experiment 1·2 c.m. of the gas mixture gave 1·4 gm. of a yellow oil not miscible with water, and water-soluble acids equivalent to 0·33 gm of potassium hydroxide. The steam distillate from this solution of potassium salts of the acids, on distillation through a column, gave about 0·5 c.c of a pleasant smelling liquid with a boiling range of 74-80° C. This liquid possessed a ketonic odour and gave the iodoform reaction in the cold, but did not readily reduce ammoniacal silver nitrate. Reducing substances were present in the aqueous part of the fractionated liquid. There was also formed 0·5 gm. of solid which blackened on exposure to light and air.

The theory of the intermediate formation of carbides advanced by Fischer does not suffice to explain the formation of oxygenated compounds.

It is possible that the hydrocarbons he obtains are formed by the dehydration of alcohols followed possibly by hydrogenation, but again this does not explain the absence of acids and ketones from the products obtained by him at atmospheric pressure.

If the view is accepted that catalysis is an acceleration of reactions already taking place, then the formation of organic substances, other than methane and carbon dioxide, must depend on the preferential acceleration of the definite reactions which give rise to them. In the case considered here the question is complicated by the probability that not only does hydrogenation take place, but also oxidation, dehydration, and possibly polymerisation.

The reaction stages, if any, which lead to methane from carbon monoxide and hydrogen are possibly

$$CO + 3H_2 \rightarrow CH_2O + 2H_2O \rightarrow CH_3OH + H_2$$
$$\rightarrow CH_4 + H_2O$$

and

$$CO + H_2O \rightarrow CO_2 + H_2$$

Up to the present, however, the formation of formaldehyde and methyl alcohol has not apparently been established at ordinary pressure without the intervention of extraneous sources of energy such as ultra-violet light, X rays, etc

The formation of oxygenated compounds and hydrocarbons may also be regarded as being preceded by the hypothetical formation of methyl alcohol, which is converted, according to the catalyst and the experimental conditions, into methane or into other substances. Thus the reaction may proceed in consecutive stages or the catalyst may accelerate one or more of the thermodynamically possible reactions from carbon monoxide and hydrogen. No doubt, where a mixed product of aldehydes, ketones, acids and hydrocarbons is obtained, both of these courses may be followed.

Manganous oxide, cobalt and copper are not generally considered to have dehydrating powers as catalysts, but Medsforth (*J Chem Soc*, 123, 1452, 1923) has explained the action of nickel in methane formation as being partly of a dehydrating nature, while the addition of oxide with dehydrating properties leaves the nickel more free to accelerate the hydrogenation stage of reaction. Nevertheless, we are of the opinion that the majority of the products obtained, in which acids, alcohols, ketones, aldehydes and hydrocarbons are all probably present, are formed simultaneously rather than consecutively Carbon dioxide, water and methane would have to be considered in formulating chemical equations for the reactions involved.

The Spark Spectrum of Lithium.

IT has been shown by Schuler and the present author that the first spark spectrum of lithium (the Li II spectrum) is of the same type as the arc spectrum of helium and consists of two spectral systems. In a letter published in NATURE of October 17, 1925, a scheme of those terms of the lithium spark spectrum was given, which must be considered as analogous to the terms of the ordinary 'doublet' spectrum of helium (the orthohelium spectrum). In this note the results of further research on the lithium spark spectrum will be given. A number of new spark lines has been found which makes it possible to establish a series scheme of the terms of the lithium spark spectrum which are analogous to the terms of

the singulet spectrum of helium (the parhelium spectrum).

To distinguish between the two spectral systems it is proposed to denote the system, which by analogy with the parhelium spectrum must include the normal state of the spectrum, the p-system of the lithium spark spectrum (abbreviated the Li II p-spectrum), while the other by analogy with the orthohelium spectrum will be denoted as the o-system of the lithium spark spectrum (the Li II o-spectrum). As observed first by Schüler (*Ann. d. Phys.*, 76, 292, 1925), and confirmed by recent observations by the author, the Li II o-spectrum is not a doublet spectrum, but seems to be a triplet spectrum of a type different from the ordinary triplet spectra.

Table I. gives the wave-lengths of the lines belonging to the Li II p-spectrum, and their series notation. The numbers in brackets are the estimated intensities of the lines, relatively to the lines of the o-spectrum given in my former letter (*l.c.*). It will be seen that the p-spectrum as a whole is considerably weaker than the o-spectrum. A similar behaviour is observed in helium under the same conditions of discharge, the parhelium spectrum being weaker than the orthohelium spectrum. Table II. gives the terms derived from the lines in Table I., with the effective quantum numbers (n^*) added in brackets.

TABLE I.

5037·8 (1).	$3P$-$4S$	2952·7 (0·5)	$3S$-$5P$
4788·8 (1·5)	$3P$-$4D$	2767·0 (1)	$3P$-$6D$
4677·7 (2)	$3D$-$4F$	2730·7 (0·5)	$3D$-$6F$
4156·3 (0·5)	$3S$-$4P$	2508·9 (0·3)	$3D$-$7F$
3305·2 (0·5)	$3P$-$5S$	1681·8 (2)	$2P$-$3D$
3249·8 (1)	$3P$-$5D$	1755·4 (3)	$2P$-$3S$
3199·4 (1·5)	$3D$-$5F$		

TABLE II.

$3S$ = 51300 (n^* = 2·925)	$3D$ = 48803 (n^* = 2·999)
$4S$ = 28484 (n^* = 3·926)	$4D$ = 27448 (n^* = 3·999)
$5S$ = 18080 (n^* = 4·927)	$5D$ = 17464 (n^* = 4·999)
	$6D$ = 12200 (n^* = 5·990)
$2P$ = 108264 (n^* = 2·014)	
$3P$ = 48328 (n^* = 3·014)	$4F$ = 27434 (n^* = 4·000)
$4P$ = 27244 (n^* = 4·014)	$5F$ = 17550 (n^* = 5·000)
$5P$ = 17440 (n^* = 5·017)	$6F$ = 12193 (n^* = 6·000)
	$7F$ = 8057 (n^*

The value of the term $2S$ has not been found. An extrapolated value of this term ($2S$ = 120000) shows that the line $2S$-$2P$ is in the infra-red at about λ8500 Å.U., and for $2S$-$3P$ (λ about 1400 Å.U.) no line has been observed which with certainty could be ascribed to this transition. It is not possible to give the value of the $1S$-term corresponding to the normal state. The excitation potential of the $2s$-$2p$ line seems to be about 60 volts, and from this the ionisation potential for the Li^+ ion can be estimated to be about 70 volts, which gives the value 550000 for the $1S$-term and for n^* a value between 0·85 and 0·90.

The scheme given in Table II. is in good agreement with the theoretical expectations. For the theory of the spectrum of an atom with two electrons, the reader is referred to a paper by W. Heisenberg, soon to appear, and a paper by I. Waller.

A remarkable feature is that the two strong lines 2934 Å.U. first reported by Mohler, and the line 3715 Å.U. first reported by Schüler, seem, contrary to what was previously assumed, not to belong to the series of the ordinary lithium spark spectrum. From a kind communication from Dr. Paul Foote, the author learns that Dr. Schüler has arrived at the same conclusion.[1] The excitation voltage of these lines is nearly the same as that of the strong green Li II- line ($2s$-$2p$). In addition to these two lines, two rather strong lines at 4607·4 Å.U. and 2337·0 Å.U. have been observed, which seem to be of the same character.

Phys.*, **37**, 568, 1926) has appeared, containing the results of his recent measurements in the Li II p-spectrum. The results given in his paper and in the present note confirm and supplement each other. S. W.

The Distribution of Red Algæ in Relation to Illumination.

WE have recently been engaged in photo-electric measurements of submarine illumination, as a result of which certain conditions governing the distribution of algæ have become evident.

The illumination in the water is reduced in amount and altered in spectral character, and these effects are composite. First, there is the absorption due to the water, as such, which results in the longer wave-lengths being reduced in far greater proportion than are the blue and violet. Grein has shown how surprisingly large the ultra-violet transmission may be in very clear water. Secondly, there is the non-selective absorption due to gross particles in suspension; this merely reduces the illumination and might be more correctly termed scattering or reflection than absorption; but as it can only be measured by the absorption coefficient of the water as a whole, the term absorption is used. Thirdly, there is the selective absorption or scattering due to very small particles, which have most effect upon the ultra-violet, violet, and blue. Fourthly, there is the selective absorption due to any tint in the water occasioned by substances in solution, as in the clear amber water of bog pools.

Determinations of the coefficient of absorption were made under various conditions by means of a photo-electric cell sensitive mainly to the blue. Values of μ were obtained as follows: near shore, with water obviously sandy, μ = 0·81; same spot in calm weather, μ = 0·105; about 20 miles from land in calm weather, μ = 0·110. Consider now the illumination at 10 metres depth, taking that immediately below the surface as unity; with sandy water the illumination at 10 m. was only 0·033 per cent., on the calm day it was 19·2 per cent. and 20 miles out 33·5 per cent. In pure water 37 per cent. of blue light of 4750 Å.U. is transmitted to about 50 m., and the same percentage of light of 4490 Å.U.—the most sensitive region for the cell used by us—to about 82 m.; on the other hand, only 19 per cent. of red light 6000 Å.U. is transmitted by pure sea water to 10 metres, a depth at which we found 33·5 per cent. of blue light for actual sea water 20 miles off shore.

It is thus obvious that the selective absorption of the water, as such, is most noticeable in clear water in which there is absolutely no tint and the grosser particles are much reduced in number save for the plankton organisms themselves. The red end of the spectrum being cut out, the light remaining is largely blue in clear water, so red algæ—which appear black to the eyes of a diver—are obviously efficient absorbers of light; they flourish, therefore, in clear water, where their red pigment is an adaptation that enables them to utilise to advantage the blue light present in reduced amount. In fresh water, however, such clear conditions are rarely encountered, and algæ with red pigment are conspicuous by their absence.

It is true that Paschen has recorded that in Alpine lakes flagellates and Cyanophyceæ with red spotted olive green and, finally, deep red are found at about 10 metres and downward, but there is no general development of algæ with red pigment in fresh water,

simply because at the depth at which the water, as such, would have left light preponderatingly blue, the gross particles would have reduced the illumination to less than that at which plants could survive. The presence of a selectively absorbing tint and of finer particles also reduces the blue light.

Evidence as to the relatively great turbidity of fresh-water lakes is afforded by measurements with the Secchi disc. Southern and Gardiner found that in Lake Atorick, which is supplied by drainage from bogs, the maximum depth for visibility was 3 m., for Lake Derg, 10 miles from the entry of the River Shannon, 4·8 m., for a very clear lake, Loughrea, 10·3 m. Values for certain lowland European lakes range from 0·2 to 7·25 m., according to Thomasson. In the sea, however, off Plymouth, Russell has found 13 m. in April to more than 20 m. in June, and values up to 50 m. are not uncommon in the open sea. Moreover, most of the fresh waters are subjected to periodical floods, with increase in turbidity. Only rarely, therefore, would the possession of a red pigment be of any service to fresh-water plants.

The Caryophyllene Alcohols and their Occurrence in Nature.

IT is a well-known fact that most hydrocarbons of the terpene and higher terpene classes are associated in Nature with corresponding alcohols from which the hydrocarbons themselves can be derived by removal of the elements of water. It is very probable, indeed, that these unsaturated hydrocarbons are actually produced in the plant by this method. Now, with the exception of cadinene, caryophyllene is probably the most widely distributed sesquiterpene in Nature, and it has therefore long been a matter of surprise that caryophyllene alcohol (which may readily be prepared from caryophyllene by Wallach's hydration method) does not occur naturally. The author knows of no recorded discovery of this alcohol in essential oils.

A study of the chemistry of caryophyllene, however, and in particular some work carried out recently in this laboratory (Henderson and Robertson, *Jour. Chem. Soc.*, 1926, 62-70), throws considerable light on this problem. Briefly, it has been established that Wallach's hydration method effects ring closure in the caryophyllene molecule with the production of a tricyclic structure. The reaction is not reversible, and the dicyclic caryophyllene structure cannot again be derived from the alcohol and its derivatives. The alcohol and its esters, therefore, possess a different configuration from that of caryophyllene, and hence could not be expected to occur as parent compounds of this hydrocarbon.

This may be said to explain the non occurrence of caryophyllene alcohol in Nature. Another interesting result of this work, however, has recently been brought to my notice. In the paper referred to above, a new caryophyllene alcohol, called caryophyllol, was synthesised directly from the hydrocarbon, and was shown to retain the dicyclic caryophyllene structure. Caryophyllol, therefore, and not Wallach's hydrate, we would expect to find occurring in plants as the natural parent of caryophyllene, and this surmise appears to be justified by some work of Semmler on an oil drawn from clove stems (*Ber.*, 1912, 45, 1392). In the higher boiling fractions he discovered a bicyclic sesquiterpene alcohol the properties of which are practically identical with those of the synthetic caryophyllol, as the following figures show:

	b p.	$d.^{17\cdot20°}$	$_{-}^{17\cdot20°}$	[R_L
Semmler's alcohol from clove stems . .	138-148° at 8 mm.	0·9681	1·50	68·18
Synthetic caryophyllol	142-150° at 10 mm	0·9632	1·5015	68·03

The agreement is the more striking in that the boiling-point and density of these compounds are both lower than is usual with alcohols of this class, and are therefore the more characteristic.

It is hoped that further work will establish the chemical identity of these two alcohols, although the experiments may be complicated owing to the theoretical possibility of four closely related isomers. In the meantime it may with some safety be predicted that caryophyllol will be found to occur in the higher boiling portions of other essential oils which contain caryophyllene.

The Reversal of the Hydrogen Series in the Extreme Ultra Violet.

IN the course of the presentation of a paper on the spectrum of neon at the spring meeting of the American Physical Society a year ago, I mentioned that I had been able to obtain the first three members of the hydrogen series in the extreme ultra-violet reversed. Recently I have repeated the experiment with the purpose of improving the technique and confirming the results.

In the first place, it is necessary to produce a continuous spectrum in the region in question; I have already described briefly how this may be accomplished (*Astrophysical Journal*, vol. 60, July 1924, p. 2). The procedure consists in charging a condenser of about 0·5 micro-farad capacity with a direct current and then discharging it through a vacuum tube of the internal capillary type arranged in series with a half-centimetre spark gap. The best results are obtained with a discharge tube of common glass. It is important that the capillary be not too large: I have found a diameter of about a millimetre satisfactory. The material of the electrodes is not important: I have employed tungsten.

The continuous spectrum seems to owe its existence to the disintegration products of the glass set free by the erosive action of the discharge, its strength depends scarcely at all on the nature of the gas in the discharge tube. The experiment is not without mechanical difficulties, for the slit of the spectroscope frequently becomes plugged up by glass dust, the removal of which involves a troublesome process.

Once the conditions for producing the continuous background have been secured, the best results were obtained by admitting hydrogen into the discharge tube at a pressure of about one millimetre. Upon applying the explosive condenser discharge, the first four members of the series—1215·6, 1025·8, 972·5, and 949·7—appear on the photographic plate sharply reversed. It is not necessary to employ pure hydrogen, however; the first two members of the series have been obtained with helium containing a trace of hydrogen. The nature of the apparatus is such (*Astrophysical Journal*, vol. 60, p. 8, 1924) that a distance of about one centimetre separates the end of the capillary from the slit of the spectroscope, while the gas which fills the discharge tube is removed from the light path by a pump the inlet of which lies two

centimetres on the grating side of the slit. The path length available for absorption is thus of the order of three centimetres. It seems certain that a very small quantity of hydrogen is sufficient to produce the reversal of the lines. THEODORE LYMAN.

Jefferson Laboratory,
Harvard University,
June 29.

Plastic Deformation of Single Metallic Crystals.

IN a letter to NATURE (May 22, 1926, p. 720), Messrs. W. E. Millington and F. C. Thompson have proposed a formula for the angle of a uniform wedge formed by the fracture of a single metallic crystal, which purports to be more general than that given by the writer in connexion with the fracture of tungsten single crystals, (*Phil. Mag.*, Aug. and Nov. 1924). By the use of this formula they consider it "possible to extract from the experimental results obtained on these single crystals of tungsten information with regard to the distance through which the atoms move and the number of planes involved which has hitherto remained unrealised."

The writer would like to point out that the use of their formula presupposes a type of slip which is inconsistent with experimental fact and that consequently it is inapplicable as a theory of wedge formation.

They have assumed that slip takes place on two sets of planes equally inclined to the specimen axis, and that the wedge angle depends only on the extent of slip per plane and the distance apart of the slipping planes. It has been shown, however, that a minimum extension of the crystal is required in such a case if fracture is to take place (*Phil. Mag*, pp. 234-235, Aug. 1924), from which it follows that a definite wedge angle (39° approx.) must result if the two halves of the divided crystal are symmetrical; and further, that if a wedge were formed in one half of the crystal with an angle greater than 39°, a wedge having an angle less than 39° must be formed in the other half. Such unlike wedges are not found by experiment; either the wedge angles were both 39° or both were greater than 50°.

The explanation of the 39° wedges is based on a purely geometrical argument and tells us nothing about the extent of slip per plane or the distance apart of the slipping planes other than that on the average they give the theoretical wedge form. The explanation of the large wedge angles given by the writer, although it may not be entirely satisfactory, was at least based on the experimental fact that they were always associated with crystals asymmetrically inclined to the specimen axis—a case which Messrs. Millington and Thompson did not consider.

F. S. GOUCHER.

New York City, June 30.

Use of Pith Dust in Kundt's Tubes.

DURING the summer of 1924, while experimenting at Indiana University with a Kundt's tube, I discovered that the striæ could be most readily observed by using pith dust in the tube. I obtained the pith dust by grinding dry pith from sunflower on a fine-grained emery wheel. By the use of this dust I was able to obtain discs that extended completely across the tube and having the same diameter as the inside of the tube.

These striæ were obtained by the ordinary method used with a Kundt's tube, but for demonstration purposes I found the following to be an excellent way to produce them: Some pith dust was placed in a glass tube of any convenient length and diameter. In one end of the tube a stopper was placed and the open end of the tube was inserted in the open end of a sounding organ pipe. When the tube was inserted the proper distance the striæ formed at regularly spaced intervals and showed the nodes and loops in an excellent way. Discs apparently but one particle in thickness were formed, and when the tube was carefully adjusted with regard to the distance to which it was inserted into the organ pipe, the separate particles remained almost motionless. Often they wove themselves into thin sheets, and when the air was turned off they fell over, maintaining the sheet form.

Egyptian History.

HISTORICAL truth compels me to remark that it is inexact to say that the dating by the Egyptians is only "*modern* calculations" (NATURE, June 5, p. 788). All three ancient versions of the lists of kings named by Manetho also state the totals of each of the three great periods; excepting the last, which is not in dispute, only named in one version. These totals count up to Alexander. Where these lists can be checked by external sources they show that overlapping periods of rule were eliminated. It is quite impossible to discuss the details here, but at least the facts justify my statement of the Egyptian reckoning. FLINDERS PETRIE.

The Bose Research Institute, Calcutta.

IN view of the lively interest that has been aroused by the lectures that have been delivered recently by Sir J. C. Bose in London and elsewhere, on the methods and results of his investigations on the physiology of plants, it will no doubt be agreeable to many readers of NATURE to have some general information concerning him and his work, and about the Research Institute which he has founded in Calcutta.

Already a B.A. of the University of Calcutta, possessing a fair knowledge of physics and chemistry, Sir Jagadis Bose came to England in 1880 for the purpose of studying medicine, and entered University College, London, where he made his first acquaintance with biology in the course of instruction given by Sir E. Ray Lankester. However, he soon found that his health, then somewhat precarious, could not stand the strains peculiar to medical study, and decided to go to Cambridge in order to devote himself to natural science. Accordingly he presented himself as a candidate for an open scholarship at Christ's College, to which he was duly elected, and went into residence there in January 1881. At Cambridge he pursued the general course of work for the Natural Sciences Tripos: he studied chemistry, and especially spectroscopy, under Liveing; physics under Lord Rayleigh in the then newly erected Cavendish Laboratory; physiology under Michael Foster; embryology under Francis Balfour; botany under Vines, who was also his college tutor. He took his B.A. degree in 1883: in the meantime he had taken his B.Sc. at the University of London, and ten years later the D.Sc. degree was conferred upon him. He thus acquired a good all-round scientific education, with a special knowledge of physics.

On returning to India in 1884, Sir Jagadis was appointed officiating professor of physics in the Presidency College, Calcutta, on the recommendation of Lord Ripon, the then Viceroy. As the value of his work came to be appreciated, he was soon raised to full professorial rank. This office he continued to hold until 1915, when he retired with the distinction of emeritus professor.

Whilst adequately discharging the onerous duties of his office, Sir Jagadis carried on research as actively as circumstances permitted. He produced a series of papers on electrical subjects which were communicated to the Royal Society by the late Lord Rayleigh, his former teacher, and made his first appearance as a lecturer in England with a discourse on "Electric Waves" at the Royal Institution in 1896, which he soon afterwards repeated in Paris and in Berlin.

At this point came the widening of Sir Jagadis' horizon to include living as well as non-living matter. He incidentally observed, in the course of his researches, that the metallic receivers of the electric waves showed 'fatigue' after prolonged service, and regained their activity after a period of rest; and conversely, that they became inert after too long a rest, but could be revived by an electric shock. He was so struck by the close resemblance of these phenomena to those presented by living muscle and nerve under similar conditions, that he proceeded to make a series of comparative experiments, the results of which were embodied in his book, "Response in the Living and Non-Living" (1902). It is there established beyond doubt that metals (but apparently no other form of non-living matter) possess to a certain degree the 'irritability' which had hitherto been regarded as peculiar to living protoplasm. When a nerve is stimulated, whether electrically, mechanically, or thermally, it gives an electrical response of negative variation. The amplitude of the response can be made to vary by changes in the conditions; it is increased, within limits, by a stronger stimulus, by a rise of temperature, or by treatment with stimulant substances; it is decreased by weakening the stimulus, by lowering the temperature, or by treatment with depressant substances; it can be altogether arrested, either temporarily or permanently, by excessive heat or cold, or by treatment with poisons. All these reactions Sir J. C. Bose obtained with strips of metal. This leads to the remarkable conclusions that 'irritability' is not exclusively the property of living matter: that the 'negative variation' response to stimulation is not a sign of 'life.' Irritability would appear to indicate a certain unstable molecular constitution common to metals and to protoplasm: the negative electric variation, to be the expression of molecular disturbance due to stimulation.

In the book to which reference has been made, the first evidence was given that not only the 'sensitive' plants, as was already known, give this electric response, but also that all plants, and all parts of plants, do so. It was made clear that all plants are sensitive, though only the so-called 'sensitives' are conspicuously motile. The novelty of the idea led Sir Jagadis to devote himself more to the biological than to the physical side in his further investigations; and rather to plants than to animals, because the physiology of animals had advanced much further than that of plants. Progress in the study of the physiology of plants had been hindered by the too mechanical conception of it that had prevailed: it seemed to have been forgotten that both animals and plants consist essentially of protoplasm, and that they must therefore present essentially the same reactions, though modified by special adaptations.

Inspired by this principle, Sir Jagadis proceeded to investigate the irritability and movements of plants by applying the methods that had yielded such fruitful results when applied to animals, and devised apparatus of special sensitiveness for the detection and automatic record of their less vigorous response. His results and conclusions have been published in a series of books, in a number of papers in the *Proceedings*, and in the *Transactions of the Royal Society*, of which he was elected a fellow in 1920; and in the *Transactions of the Bose Research Institute*, of which four volumes have appeared (1918–21).

Without going into too much detail, a few of Sir Jagadis' most striking researches and discoveries may be mentioned. For example, his book "The Physiology of Photosynthesis" (1924) gives the most satisfactory extant account of a process which is of cosmic importance. In his "Physiology of the Ascent of Sap" (1923), he brings forward convincing experimental

evidence that the sap is raised in the tree-trunk by the active contraction of special propulsive cells, the position of which he was able to localise by the electric probe, which he originally devised for the detection of the geo-perceptive layer of cells in stems and roots, a conclusion which is still strongly contested by the adherents of the traditional physical explanation of the process. His most recent book, "The Nervous Mechanism of Plants" (1926), brings together all the evidence scattered throughout previous works that the conduction or transmission of excitatory impulse in plants is a physiological process and is limited to a particular tissue, certain elongated tubular cells of the bast in the vascular bundle, which may justly be termed 'nerve,' in opposition to the current view that the process is purely mechanical and that the tissue concerned is the wood. The conducting tissue in the stem and leaf was located by the electric probe, which again did good service, and the physiological nature of conduction is established by the observation that, in the plant as in the animal nerve, conduction is affected by changes of temperature, by blocking and by stimulating agents, which could not have any such effect upon it were it merely mechanical. A special account is given of the nervous arrangements in the motile leaf of the sensitive *Mimosa pudica*, in which reflex action is demonstrated.

Taking together this book and that on the ascent of sap, it may be generally stated that Sir J. C. Bose's researches have established the existence in the vascular plants, at least, of a circulatory and of a nervous system, using the terms in a loose general way. The 'circulatory system' includes neither heart nor veins, consisting entirely of strands of propulsive cells distributed throughout the plant, representing a contractile arterial system: similarly, in the 'nervous system' there are no central organs, such as brain, spinal cord, or even ganglia, only nerves, of which some have been shown to be sensory, others to be motor. No doubt there remains much yet to be discovered along these various lines of research.

The Research Institute at Calcutta (Fig. 1) was founded and built by Sir J. C. Bose as a place where he and his students and their successors might continue to carry on the researches of which some account has been given above. It was publicly inaugurated on November 30, 1917, and has been in active operation ever since. It is a beautiful and commodious building, standing in its own spacious grounds, with all the details of its construction and arrangements carefully thought out to ensure its perfect adaptation to its purposes. There is a large auditorium capable of accommodating 1500 persons, a library, and rooms and laboratories for work of various kinds. No elementary teaching is undertaken: the only object in view is post-graduate research. The carefully selected scholars, of whom there are at present about sixteen, are admitted on the condition that they devote themselves wholly to the prosecution of research, not as a means of livelihood or for the satisfaction of personal ambition, but, in the words of the founder, "in order to realise an inner call to devote one's whole life to the infinite struggle to win knowledge for its own sake and to see Truth face to face." They receive a modest allowance for their maintenance so that they may be free from distracting cares. The line of research pursued is essentially physiological in its direction, and includes both animal and plant in its scope, though so far the plant has received more

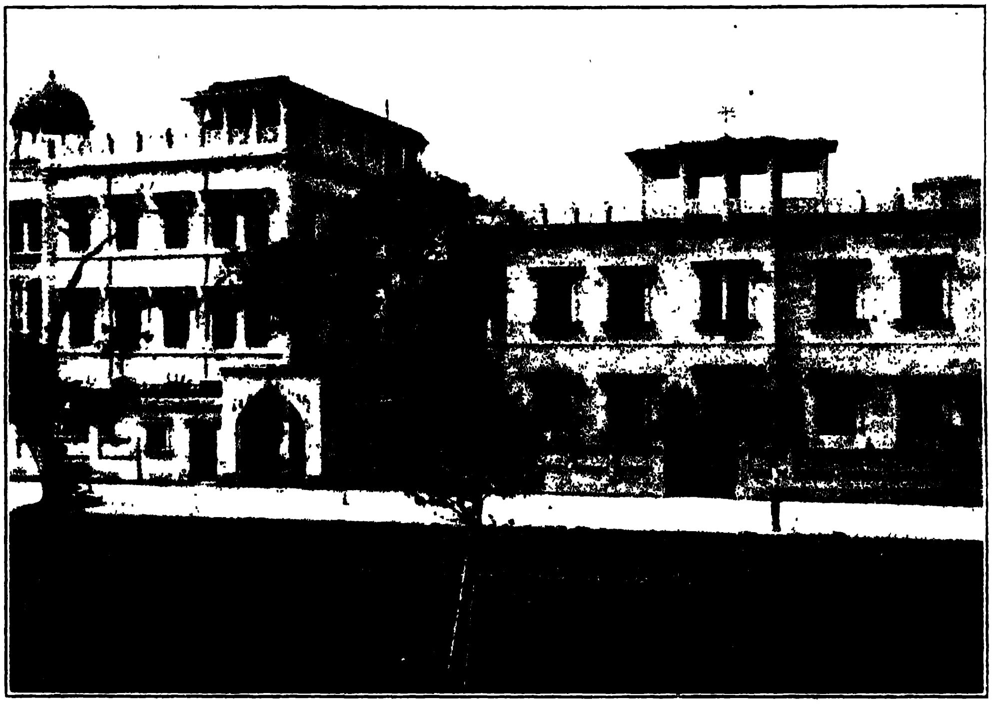

FIG. 1.—The Bose Research Institute, Calcutta.

attention than the animal. But it is physiological in the widest sense, encroaching, as occasion arises, on physics, on bio-chemistry, on botany and zoology, and on histology. At the present time there are no workers at the Institute other than the staff and the scholars, but it is the hope and desire of the founder that it may be frequented by students from all parts of the world, who are assured beforehand of a hearty welcome and of a hospitable reception.

The foundation of the Research Institute in Calcutta, as well as of the branch, Mayapuri, situated at Darjiling at 7000 ft. elevation, in an altogether different climate, was due, in the first instance, to the munificence of Sir J. C. Bose; since then, considerable sums have been contributed by Indian princes and others for extensions and for endowment. The Imperial Government of India has recognised the value of the services rendered by the Institute to the advancement of science by making an annual grant out of public funds for its upkeep. The Institute has continued from the beginning to expand both materially and intellectually. It has shown what important results can be obtained by the combination of the logic and the scientific methods of the West with the imagination and the idealism of the East. Even now it is still only at the beginning of its career, a career, let us hope, of ever-increasing usefulness and brilliance, which ought to be assured by the principles of self-abnegation upon which its constitution is based, more than fulfilling the most sanguine expectations of its founder and reviving the ancient reputation of India as a home of learning.

The Lewis Evans Collection at Oxford.

Recent Additions.

WHEN the oldest of British museums was re-opened for the scientific treasures presented to the University of Oxford by Dr. Lewis Evans, it was foreseen that that fine collection must act as a lodestone and attract cognate objects to itself. This expectation has been realised in a remarkable measure by gifts and loans of apparatus, and by the discovery and reconstruction of long-forgotten instruments. The first fruits of the reversion of a part of the Old Ashmolean building to its original use as a Science Museum are now on exhibition.

Several colleges have contributed apparatus that is second to none for illustrating the early history of many scientific inventions. Both Merton and Oriel Colleges have proved themselves faithful custodians of the quadrants and astrolabes of their astronomer fellows of the fourteenth century. No other educational institution can boast continuous possession of scientific appliances for so many centuries. Contemporary manuscripts written about these very instruments, describing their use, collected when the instruments to which they refer were three centuries old, were given by Ashmole to be "preserved in the presses" of his Science Museum, that his good name might endure "for all time." There they remained for yet another two hundred years, while the instruments, to the use of which they supplied the key, languished in college chests and cupboards. To-day the instruments are on exhibition in Ashmole's building, while Ashmole's own books about them have been put away out of sight in hidden recesses in buildings other than those named in his will. If both books and instruments were once again placed side by side, we should have visible proof of the scientific pre-eminence of the Merton School in the fourteenth century.

To a distinguished fellow of Merton we owe the beginning of our technical scientific literature. Richard, the son of a blacksmith at Wallingford, received a practical education that enabled him in 1326 to compose in terms as clear as those of a proposition of Euclid, a model treatise, the first of its kind known to have been written by an Englishman, upon "How to Make" a scientific instrument. He prescribed the exact dimensions of the metal parts, both in the rough and in the finished state; and he illustrated the shaping and fitting by working diagrams, so that it is possible to interpret his meaning after six hundred years. His distinction as a man of science led to ecclesiastical preferment. Richard, the maker of our first recorded astronomical clock, became abbot of St. Albans. His 'rectangulus,' figured in NATURE for January 12, 1924, has been partly reconstructed this very year in honour of the sixth centenary of his original invention.

Two centuries later the needs of Elizabethan navigators and gunners advanced the skill of the instrument maker to higher levels, both of execution and of invention. By the generosity of the University Court of St. Andrews, there is on view the finest astrolabe known to have been made by an English craftsman. It is 2 feet in diameter, and 33 pounds in weight. It is inscribed with the name of its maker, Humphrey Cole of London, and is dated with the day of the month, May 21, 1575, the very year when he was getting ready the instrumental outfit for Martin Frobisher's first expedition in search of the North-west Passage to Cathay, an enterprise in which Elizabeth herself was financially interested to the extent of 1000*l*. By the finding of Cole's great astrolabe we have proof for the first time that there were in London craftsmen capable of executing work equal in quality to that of the instrumental equipment of the best-endowed observatory in the world, the astronomical observatory of Tycho Brahe at Uraniborg. Nor was this Cole's only claim to a place in our memory. He was the first Englishman to engrave a copperplate map for the illustration of a book, the Bishops' Bible of 1572. The advent of the Lewis Evans collection has also led to the discovery of one of Cole's early theodolites in the Library of St. John's College. This discovery proves him to have been the maker and improver, if not the original designer, of our premier surveying instrument, an invention usually associated with the name of Leonard Digges of University College.

A century later and we come to the epoch of the great experimenters, too soon to be followed by the epoch of the great destroyers. The Royal Society, finely equipped in the days of Daniel Colwall and Grew

with a repository of scientific apparatus that would now have the utmost historical value, has neglected and scattered the instruments of its great alumni, Boyle, Wren, Hooke. A fashion has been set of undervaluing scientific treasures left in trust, the latest examples being the dispersal of the Crisp collection of Microscopes, of the Howard Library (by the Royal Society), and of a part of the Library of Sir Isaac Newton.

The Lewis Evans collection has afforded an opportunity of trying to stem the current of our losses, and by the construction of models illustrating certain aspects of the work of the first Oxford fellows of the Royal Society. Models of Wren's perspectograph and level recall his method of dealing with problems presented by the devastated areas in the Metropolis after the Great Fire of 1666. A model of Hooke's microscope recalls what was perhaps the greatest achievement of that universally inventive genius, the first discovery of cell structure in living beings. In another case is an exhibit illustrating the first discovery of oxygen in 1668 by John Mayow of Wadham College. A model of Boyle's first airpump reminds us that it was the High Street in Oxford that produced the first English engine to demonstrate the possibility of harnessing the force exerted by atmospheric pressure, the "spring of the air," as Boyle called it. Other models show how the dwellers in an inland town have been able to teach and assist navigators: Hooke's reflecting instrument, Gunter's cross-staff and sector, the magnetic compasses of 1269 of Peter Peregrinus, and of 1750 of Gowin Knight of Magdalen College being notable examples, paralleled in our own time by the instruments invented for seamen by Lord Kelvin.

Space will not permit us to rehearse all the exhibits in our small Museum, but in truth we may define it as a school of gratitude to the great men who have increased the knowledge and the power of the human race. The most recent of the reconstructions is a beautifully made astrolabe designed by Prof. Frewen Jenkin, for making known the virtues and uses of that 'mathematical jewel' to a wider public than the favoured few who possess original examples. In this regenerated form, the astrolabe again becomes an instrument of great educational value.

The enterprise of museum founding has not been without its disappointments. First and foremost was the dispersal of the collection formed by Sir Frank Crisp to illustrate the evolution of the microscope. Through the kindness of Sir John Findlay, one of the masterpieces of that collection, a superb silver instrument by Adams, is on view in Oxford for the meeting of the British Association. But the general disappearance of much good apparatus in Oxford itself is deplorable. Only a few months ago there were in existence things of great scientific interest which have vanished. A model with which Bradley illustrated his discovery of the aberration of light is not now forthcoming. Antique microscopes, barometers, the paraphernalia of the educational methods of a century of preparation for the great scientific advances of to-day, have gone to the scrap heap—destroyed in many cases by the urgent needs of research in hand. In the modern laboratory there is no place in which to store the apparatus of bygone experimenters, even if there were a desire to keep it intact, rather than to make use of its parts.

It is our plea that scientific instruments that are of value, either for beauty of design, for achievement in the laboratory or lecture-room, or for some other good cause, should at least be treated with the respect that is accorded to early editions of printed books in a library, or to pictures in a gallery of art. The destruction of a copy of an old book that has been printed in hundreds and reprinted in tens of thousands, inflicts no great harm on the world of letters, but the loss of a unique instrument obscures the whole meaning of early work. Only by contemporary scientific appliances can we hope to show to future generations the ever-varying fashions and phases of our natural philosophy: and few objects are better worth the effort, for in our northern civilisation, natural science has become of greater consequence than art. To traverse the long galleries of the museums of arts and crafts, and to study their masterpieces, is a dispiriting pilgrimage, for it brings home to one how slight is the influence that such exhibitions exercise in elevating the art of a modern people. Scientific instruments, too, show regression in respect of their art: but they show continuous advance in respect of their science.

All work of preservation is of the utmost value in that it helps to check a tendency to destroy evidences of our own early civilisation, and to remind us that with our now diminished resources, instead of spending large sums on the conservation of relics of antiquity abroad, it may pay better to honour the prophets of our own country.

R. T. G.

The Oxford Meeting of the British Association.

MEMBERS of the British Association visiting Oxford during the forthcoming meeting will find themselves in the midst of a south midland district which is, from the naturalist's point of view, possessed of great and varied interest. Opportunities will be given by means of sectional excursions for gaining such acquaintance as may be possible with the geology of the surrounding country, and with noteworthy features of its characteristic fauna and flora. It is obvious that no extended study of the district can be undertaken in the short time at the disposal of those attending the meeting, but the "Handbook" which will be distributed to all visiting members of the Association will provide them with a summary, under various heads, of what the neighbourhood of Oxford can show in the way of natural features of interest.

This handbook, the work of several authors, each of them a first-rate authority on the subject with which he deals, is being produced under the editorship of Commander J. J. Walker, R.N., and will no doubt take rank as a volume of permanent value. It begins with an account by Mr. H. O. Beckit, director of the School of Geography, of the physiography of the Oxford region, including a definition of its boundaries, and describing its land forms and physical history. Sections are added by Mr. W. G. Kendrew on its climate, by

Mr. E. T. Leeds on its early and by Mr. H. O. Beckit on its modern settlement. The geology of the area is dealt with by Prof. W. J. Sollas, who devotes his attention mainly to the parts of the great Jurassic system which lie within easy reach of Oxford. Dr. K. S. Sandford contributes an account of superficial deposits, and Mr. A. J. Arkell an appendix on the Corallian Period. Articles follow on the botany, ornithology and entomology of the Oxford country; these have been treated with great thoroughness by Dr. G. Claridge Druce, the Rev. F. C. R. Jourdain, and Commander J. J. Walker respectively; the latter having as collaborators Messrs. W. J. Lucas, A. H. Hamm, E. G. R. Waters, and J. Collins. The spiders have been attended to by Mr. A. W. Pickard-Cambridge, and the land and fresh-water mollusca by the Rev. L. W. Grensted. Among the institutions for which Oxford is famous there are three of special importance for the members of the British Association. The first of these, the great entomological department, which takes its name from the late F. W. Hope, is described by Prof. E. B. Poulton; the Pitt-Rivers Museum of Ethnology is treated of by its curator, Mr. Henry Balfour; and the whole series of these valuable memoirs is wound up by Dr. R. T. Gunther's account of the Old Ashmolean Museum and the Lewis Evans collection of scientific instruments therein housed under his curatorship.

The general excursions to Swindon, Stratford-on-Avon, Warwick and Kenilworth, Burford, Fairford and the Cotswolds, Blenheim Palace, and the expeditions by river to Day's Lock, to Abington and to Reading, all have their own objects of interest; but for the special purposes of the naturalist the sectional visits to Fawler, Hanborough and Stonesfield; Kirtlington; Culham, Abingdon and Radley; Aylesbury and Wheatley; Swindon, Faringdon, etc.; Boar's Hill; Shotover and Headington (geology); Tring (zoology); and Swinford Bridge; the Berkshire Downs; Lord Parmoor's beechwoods; Bagley Wood (botany and forestry), will provide the best opportunities for studying the natural features of the district.

Apart from the excursions and exhibits which appeal more directly to the geologist and biologist, there is much in Oxford to engage the attention of visiting members. A special selection of rare and interesting works will be on view in the Bodleian Library, by the courtesy of the librarian; and a similar courtesy will be shown by the authorities of the Radcliffe Library now housed at the Museum. Special visits to colleges have been arranged, each under the direction of a guide competent to explain the historical and architectural interest of these institutions, which are such distinctive constituents of the older Universities. The Lewis Evans collection of historic scientific instruments will be shown and discoursed on by the curator; the Pitt-Rivers ethnological collection will be open to inspection, and a visit will be undertaken to the printing works of the famous Clarendon Press. Not the least popular amongst other attractions will be a demonstration on Port Meadow by the Royal Air Force. Machines of several types, with instruments and other apparatus of special interest, will be parked for inspection; a flying display will take place, and the machines will be seen to leave park and take off by flight for return to their home aerodromes.

Much interest will naturally centre round the University Museum, the early history of which structure has been graphically related by Dr. and Mrs. Vernon in an excellent little book published soon after the jubilee celebration held on October 8, 1908. To those whose recollections go back to the days when Acland and Ruskin were prominent figures in the University, the main building of the Museum is eloquent of the generous ideals of those distinguished enthusiasts. Nor should it be forgotten that without the support of Pusey and his Tractarian friends the scheme for giving the natural sciences a worthy home in the University might have been indefinitely delayed. It is true that the ideal proposed to himself by Acland, that of ensuring that every one leaving Oxford with a degree should at least have had given to him "a general view of the planet on which he lives, of its constituent parts, and of the relations which it occupies as a world among worlds," has never been realised; the growing necessity for specialisation, together with other reasons, forbade its accomplishment. But the tree planted with so much hope by Acland, Daubeny and Buckland has borne good fruit, though of a kind scarcely contemplated by its original cultivators. Of late years opposition to the growth of the Museum and its departments has usually taken the form of protest against encroachments on the open space of the University park. But a delimitation of frontier has at last been established by general agreement, and the question may now be taken as settled for very many years to come. On the present occasion the Sections of Mathematics and Physics, Geology, Zoology and Engineering, will be housed in the Museum and its annexes, while Botany will find an appropriate home in the neighbourhood of the venerable "Physic Garden." F. A. D.

DISTINGUISHED GUESTS FROM ABROAD.

Usually a number of eminent scientific workers from countries outside the British Empire are invited to be guests of the Association at its annual meeting. We print below some particulars of those who have accepted invitations for the Oxford meeting.

Prof. GEORGE DAVID BIRKHOFF, who has occupied the chair of mathematics in Harvard University since 1919, was born at Overisal, Michigan, in 1884. He early engaged in teaching mathematics in the University of Wisconsin; next at Princeton, until 1912, when he became an assistant professor at Harvard, taking up later the major post. President, in 1925, of the American Mathematical Society, he has been editor of its *Transactions* since 1920. He is a member of the National Academy of Sciences, Washington. In 1918 Prof. Birkhoff was awarded the Querini-Stampalia prize of the Royal Institute of Science and Arts, Venice, for researches in dynamics. He is the author of "Relativity and Modern Physics" (1923).

Dr. MAX BORN, professor of theoretical physics in the University of Gottingen, is one of the chief exponents of the conceptions of modern physics. A recent work of his, "Vorlesungen über Atommechanik" (1925), has received wide attention and appreciation, and an English translation is in course of preparation.

The ABBÉ BREUIL, D.Litt. (Cambridge), is chief pro-

fessor at the Institute of Human Palæontology, Paris, the foundation of the late Prince Albert of Monaco. He is the foremost authority on the art and technique of the palæolithic epoch. Prof. Breuil has collaborated in many important works on prehistoric art, and in general archæology, with MM. Capitan and Peyrony. One of the most illuminating and suggestive of his memoirs (1905) is "La Dégénérescence de Figures d'Animaux en Motifs Ornementaux à l'Époque du Renne." Prof. Breuil made lately a tour through Central Europe, Poland, and Hungary, accounts of which have appeared in *L'Anthropologie.*

Prof. DOUGLAS HOUGHTON CAMPBELL, botanist, was born at Detroit, U.S.A., in 1859. He is a foreign member of the Linnean Society, and a member of the National Academy of Sciences, Washington. Professor of botany in the University of Indiana from 1888 until 1891, he has since then occupied a similar chair in the Leland Stanford University, California. Prof. Campbell is the author of several botanical text-books.

Prof. CONSTANTIN CARATHÉODORY, University of Munich, mathematician, was born in 1873. Originally professor of mathematics in the Technical Institute, Hanover, next at Breslau, he afterwards successively occupied professorial chairs in the Universities of Göttingen, Berlin, Smyrna, and Athens. He is Ph.D. Göttingen.

M. MAURICE CAULLERY, who was born in 1868, has been professor of zoology at the Sorbonne, Paris, since 1909; formerly he occupied a similar chair in the University of Marseilles. He is director at the Sorbonne of the Laboratoire d'Évolution des êtres organisés et embryologie générale. A publicist of note, he has written on the universities of the United States, and connected scientific life. Prof. Caullery is a foreign member of the Linnean Society of London.

Prof. FRANK WIGGLESWORTH CLARKE, chemist, was born at Boston, U.S.A., in 1847. He was professor of chemistry in Harvard University, 1873–74; afterwards, down to 1883, he held the chair of chemistry and physics in the University of Cincinnati. From that date Prof. Clarke has been Chief Chemist to the United States Geological Survey, and Honorary Curator of Minerals, United States National Museum. A Chevalier of the Legion of Honour, he is a foreign member of the Geological Society of London, LL.D. Aberdeen, and D.Sc. Manchester. In 1903 the Literary and Philosophical Society of Manchester awarded him its Wilde medal. Prof. Clarke is the author of many papers on geo-chemistry in the U.S. Geological Survey's publications.

Prof. EDWIN GRANT CONKLIN, biologist, was born at Waldo, Ohio, in 1863. He graduated at Ohio Wesleyan University, and was (1891–94) professor of biology there. Since 1908 he has occupied the chair of zoology in the University of Princeton. He is a member of the National Academy of Sciences, Washington. Prof. Conklin is the author of "Heredity and Environment," "Biology and Democracy," and other works.

M. PIERRE DANGEARD is professor of botany at the Sorbonne, Paris, and director of the Botanical Laboratory there. He is a member of the Academy of Sciences, Paris, and an Officer of the Legion of Honour. Prof. Dangeard has been responsible, during many years, for an ever-constant series of memoirs and observations in general botany.

Dr. WALTHER VON DYCK, rector of the Bayerische Technische Hochschule, Munich, is also professor of mathematics in the Institute. He is the author of numerous papers on analysis, differential equations, and the theory of functions, and has interested himself in the work of the German Museum at Munich.

Prof. PAUL EHRENFEST, born in 1880 at Vienna, has been, since 1912, professor of theoretical physics in the University of Leyden. He holds a high position in the ranks of mathematical physicists, and has published many valuable memoirs, particularly ou spectra in relation to atomic structure. He is Ph.D. Vienna.

Prof. JAMES FRANCK, occupant of the chair of physics in the University of Göttingen, and director of the Physical Laboratory there, is the author of many memoirs of distinction on the atomic theory and its issues. He has collaborated with Dr. Max Born in some of these contributions in the *Zeitschrift für Physik.*

Prof. OTTO JAEKAL, Ph.D. Munich, occupant of the chair of geology and palæontology in the University of Greifswald, was born in 1863. He is well known in English geological circles, and recently was elected a Foreign Associate of the Geological Society of London. Formerly on the teaching staff of the University of Strassburg, he was afterwards curator of the Geological and Palæontological Museum, Berlin. Prof. Jaekal long rendered signal service as editor of the *Palaeontologische Zeitschrift.*

Prof. ARTHUR EDWIN KENNELLY, who has occupied the chair of electrical engineering in Harvard University since 1902, was born at Bombay in 1861. Educated at University College School, London, he early trained for service with the Eastern Telegraph Company and was engaged on cable-repairing work in many seas; also at one time he was engineer in charge of submarine cable laying for the Mexican Government. Prof. Kennelly was principal electrical assistant to Mr. T. A. Edison from 1887 until 1892. He is a Chevalier of the Legion of Honour, an honorary member of the Institution of Electrical Engineers, London, and a member of the National Academy of Sciences, Washington.

Prof. HENRY FAIRFIELD OSBORN, president of the American Museum of Natural History, was born at Fairfield, Connecticut, in 1857. He graduated at Princeton University, U.S.A. Early in his career he studied at Cambridge under F. M. Balfour, and for some time under Huxley, at the Royal School of Mines, London. Prof. Osborn was this year awarded the Wollaston medal of the Geological Society, when reference was made to his long record of researches on the palæontology of vertebrates. Important publications of his include "The Age of Mammals in Europe, Asia, and North America," and "Men of the Old Stone Age." Prof. Osborn is a foreign member of the Royal Society of London, and a Darwin medallist.

Prof. CARL RUNGE, of Göttingen, was born in 1856. Originally one of the professors at the Technical Institute, Hanover, he was appointed (1904) to the chair of applied mathematics in the University of Göttingen. He is eminent for his classical researches in spectroscopy. In 1909–10, Prof. Runge was at Columbia University, New York, as interchange lecturer.

Prof. G. MANNE SIEGBAHN, who has held the chair of physics in the University of Upsala since 1923, was born in 1886. Formerly he was a professor in the University of Lund. Nobel laureate in physics for 1924, an experimentalist of great refinement of method, his chief researches have been in the field of X-ray spectroscopy. He has made a special study of the soft radiations which lie between the ultra-violet and the ordinary X-ray region. Prof. Siegbahn is the author of "The Spectroscopy of X-rays" (Oxford Press, 1925). Published originally (1923) at Berlin, it was translated by Mr. George A. Lindsay, assistant professor of physics in the University of Michigan.

Prof. FRANK LINCOLN STEVENS, botanist, was born at Syracuse, N.Y., in 1871. He studied at Ohio State University and the University of Chicago. He occupied the chair of botany and vegetable pathology in North Carolina College of Agriculture and Mechanical Arts from 1902 until 1912, and shortly afterwards was elected professor of plant pathology in the University of Illinois, a post he still fills. He has been for many years head of the department of plant diseases and biologist in North Carolina Agricultural Experimental Station. Prof. Stevens is the author of a standard work, "Plant Disease Fungi."

Dr. JOHANNES WALTHER, who was born in 1860, occupies the chair of geology in the University of Halle-Wittenberg, Halle. Formerly he held a similar chair in the University of Jena. Dr. Walther is a foreign member of the Geological Society of London.

Prof. HENRY BALDWIN WARD, zoologist, was born at Troy, N.Y., in 1865. He is a graduate of Williams College, U.S.A., and he was a post-graduate student at the Universities of Göttingen, Freiburg, and Leipzig. He was professor of zoology in the University of Michigan from 1899 until 1909, and has since that date occupied the chair of zoology in the University of Illinois. He has long been in charge of the biological work of the Michigan Fish Commission on Lake Michigan, and has rendered good service to the United States Fish Commission. Prof. Ward is the author of "Freshwater Biology" (1917), and of many monographs and papers, especially in regard to animal parasites and the relations of animals to disease.

Geheimrat WILHELM WIEN, the distinguished physicist, rector of the University of Munich, was born in 1864. Formerly he was professor of physics in the University of Würzburg, having succeeded Röntgen in 1900. Whilst working there, Prof. Wien was awarded the Nobel prize for physics (1911); in that year Madame Curie was given the Nobel prize for chemistry. Prof. Wien accepted the chair of experimental physics at Munich, on leaving Würzburg. It may be recalled that at the meeting of the Association held in Cambridge in 1904, Prof. Wien attended and read a paper entitled "Experiments to decide whether the Ether moves with the Earth."

Prof. PIETER ZEEMAN, of Amsterdam, was born in 1865. He is a foreign member of the Royal Society of London, and in 1922 was awarded the Rumford medal for his researches in optics. Earlier (1902) Prof. Zeeman was Nobel laureate in physics, jointly with Prof. H. A. Lorentz.

Limitations of space do not allow extension of the above brief notices, but we may add that other prominent European men of science attending the meeting include M. von Frey, professor of psychology, University of Würzburg, Dr. D. Nys A. Michotte, professor of psychology in the University of Louvain, Prof. E. Rignano, Milan, Prof. H. Kniep, occupant of the chair of botany in the University of Berlin, Dr. Bosch Gimpera, University of Barcelona, the leading archæologist of northern Spain, M. Champy, professor of histology in the University of Paris, Dr. J. A. Christiansen, professor of chemistry in the University of Copenhagen, and Prof. H. ter Meulen, of Delft.

Obituary.

SIR PETER SCOTT LANG.

WE learn with regret that Sir Peter Redford Scott Lang died on July 5 at his residence at Mansefield, St. Andrews. Owing to failing health, in 1921 he had retired from the chair of Regius professor of mathematics in the United College at the University of St. Andrews, being given the title of emeritus professor, while he ever continued to show an alert and sympathetic interest in the town and college which he loved and served.

Born in Edinburgh on October 8, 1850, Sir Peter received his early education at the Institution and then studied at the University there, where he performed brilliantly in spite of the interruptions to his college work caused by the need to spend considerable time in an office. As a student so circumstanced and yet so successfully overcoming the difficulties of his twofold task, he won first the notice and later the esteem and lasting friendship of the late Prof. P. G. Tait, who appointed him in 1872 to be his assistant in natural philosophy at the University of Edinburgh.

In those days the graduate in arts was seldom proficient or even interested in the sciences; and it was notable how this youthful assistant soon acquired a wide and accurate knowledge of these fields, inspired as he was by the example of Prof. Tait. These two friends co-operated both in classroom and in the work of the Royal Society of Edinburgh, where under this guidance the younger man received much useful experience, and where in 1878 he was made a fellow.

The next year Sir Peter was called to the chair of mathematics in St. Andrews, which had just been vacated by Chrystal, who was migrating to Edinburgh. From 1879 until 1921 Scott Lang held this post with marked distinction. He devoted himself both to his teaching and also to the wider interests of college life. In this venerable University, affiliated indeed to Bologna, the oldest of medieval universities, new life was wanting. Chrystal had scarcely spent long enough time there to make his influence felt; but during the service of his successor a regeneration took place. He sought to regain that spirit of comradeship among the students which was lacking, and, thanks very largely to his unsparing energies, St. Andrews regained much of the charm and distinction which are the incidental gifts that one of the older universities bestows on its

students. He earned the honours which King and College gave to him at the close of his active career.

Miss Gertrude Lowthian Bell.

Archæological studies in the Near East have suffered a great, indeed an almost irreparable, loss by the death of Miss Gertrude Lowthian Bell, which took place at Baghdad on July 11, at the age of fifty-seven years. The eldest daughter of Sir Hugh Bell, she was educated at Queen's College, London, and at the University of Oxford, where she took a first class in the History Schools. She then went to Teheran and later began her travels in Arab countries, travels in which—a remarkable achievement for a woman—she crossed the deserts of Arabia, thereby winning for herself the gold medal of the Royal Geographical Society, and visited the Shammar stronghold at Hayil, to which no European had penetrated for twenty years. Here a detention, virtually as a prisoner, gave her a remarkable insight into Arab customs, the Arab temperament, and an acquaintance with Ibn Saud, which were to prove later of the greatest value to Great Britain. It was very largely this knowledge of Arab character which was responsible for her successful achievement as a political officer at Baghdad during the War in the Political Department of the Government of India, which was then in charge of Mesopotamian affairs.

Miss Bell was not interested in geographical exploration alone; her knowledge of eastern archæology was both wide and deep. She was particularly interested in the study of early Christian and Islamic architecture, and in 1905 and 1907 she was associated with Sir William Ramsay in an examination of the churches of Lycaonia. The results were published in "The Thousand and One Churches," of which she wrote the greater part. Perhaps her greatest service to archæology was after the War, when she had taken up her residence as a member of the Government service in Baghdad. It was largely through her efforts that excavations were so promptly resumed after the War by the British Museum at Ur and the University of Oxford at Kish, and she founded and organised the Museum of Antiquities at Iraq, in which she worked hard as a labour of love until the time of her death.

Miss Bell's knowledge of the Arab and Arab politics played a large part in the settlement of Iraq after the War. How great this knowledge was, and the qualities upon which it was based, may perhaps best be gathered by those who did not know her personally from her books. In "The Desert and the Sown" (1906) and "Amurath to Amurath" (1910) she revealed the indomitable courage, backed as it was by an iron constitution, which had enabled her to endure the hardships of the desert; but she also showed what were her most striking qualities—penetration, sympathy, and a wide knowledge of Eastern human nature, permeated with a humorous and tolerant appreciation of its foibles.

Mr. F. Harrison Glew, M.B.E.

We regret to record the death of Mr. F. H. Glew, M.B.E., which took place on July 10, at the age of sixty-eight years. Mr. Glew was educated at Wakefield Grammar School and entered engineering works in that town, but soon changed over to pharmaceutical studies and, in due course, became a member of the Pharmaceutical Society. Soon after the discovery of X-rays he became one of the pioneers of their use in medical work in England, and, for many years, he did the X-ray work for the Lambeth Infirmary, for the Belgrave Hospital for Children, and for medical men in that district.

As a pharmacist, Mr. Glew's interest was aroused by the medical uses of radium, and he occupied an important position in the radium world for many years, where his manipulative skill and chemical knowledge were put to very severe tests. During the War he was chief adviser on radium technique to the Ministry of (Optical) Munitions, his services being rewarded by an M.B.E. When the War was over, a large quantity of radium was put at the disposal of the Medical Research Council for medical investigations, and here again the services of Mr. Glew were requisitioned to deal with the technical problems involved in its use.

Mr. Glew was one of the original members of the Röntgen Society, and contributed several papers to its proceedings, but he wrote little beyond these articles and parts of the section on radiology and radium in the "Extra Pharmacopœia." He was also a fellow of the Institute of Physics and member of the Physical Society, and he served on the Board of Visitors of the Royal Institution, at all of which he gave not infrequent demonstrations. By these demonstrations, always exhibiting something novel in an ingenious way, Mr. Glew became known to a very wide scientific public; he had indeed made for himself a unique place in scientific work. His loss will be felt very much, especially by those who had learnt to look upon him with something akin to affection.

S. Russ.

We regret to announce the following deaths:

Mr. E. T. Cresson, founder of the Entomological Society of Philadelphia, later the American Entomological Society, and an authority on North American Hymenoptera, on April 19, aged eighty-seven years.

Mr G. A. Keartland, for more than forty years a member and in 1907 president of the Field Naturalists' Club of Victoria, who took part as naturalist in several expeditions to Central Australia, notably the Horn Expedition of 1894, and was known for his interest in bird-life.

Prof. Geo. D. Shepardson, professor of electrical engineering in the University of Minnesota since 1892, distinguished for his work on problems of electric lighting and telephone disturbances, on May 26, aged sixty-one years.

Prof J. C. Smock, assistant in charge of the New York State Museum and afterwards (1890–1900) State geologist of New Jersey, on April 21, aged eighty-three years.

Dr. Henry M. Whelpley, dean of the St. Louis College of Pharmacy, secretary of the United States Pharmacopœial Convention and formerly president of the American Pharmaceutical Association, on June 26, aged sixty-five years.

News and Views.

IN his speech at the opening of the exhibition of British chemical plant, held last week at the Central Hall, Westminster, in connexion with the Society of Chemical Industry's Congress of Chemists, Sir Max Muspratt referred to the ever-changing nature of the chemical industry and to the great part which chemical engineering plays in the changes. The life of the Le Blanc soda process, now extinct, was greatly prolonged by engineering, and it is that branch of the industry to which we must look to keep us abreast of the times, and more particularly in regard to the artificial fibre industry and to what is known as 'high-pressure' chemistry. As an illustration of the radical changes now taking place, Sir Max referred to a large sulphuric acid works, using the lead-chamber process, which is producing 1000-1200 tons of acid per week solely by electric power. We must learn to dispense with coal, he said. British chemical industry was built upon cheap coal and the German industry upon dear coal; now the positions are reversed, and all our old problems must be attacked from this new point of view.

THE exhibition, which was organised by the British Chemical Plant Manufacturers' Association, may be described as small but good. Owing to the restricted dimensions of the hall, it was impossible to show any large plant, but the exhibits of plant parts, constructional materials, and accessories, were so numerous and so well selected, that they presented a convincing picture of the resourcefulness and constructive ability of British plant manufacturers. From careful inquiries we have made, we can endorse the claim that at the present time practically all the requirements of British chemical manufacturers can be met at home; in a few respects, such as plant for high-pressure work, it may be necessary to go abroad, but we are gradually accumulating our own experiences in this direction and can look forward to complete independence of foreign makers within a comparatively short time.

AMONG the novelties exhibited was the Webb colloid mill, which consists of a spherical shell with three arms or beaters, circular in section and revolving at different speeds. The emulsified material is withdrawn in such a way that only the extremely finely divided material is removed. Another exhibit of a similar kind was a copper-lined machine for breaking down cotton linters in the manufacture of acetylcellulose silk. Excellent centrifugal machines, such as are used in the home beet-sugar industry, were shown, together with a clutch-pulley which enables the cage-motor to start against full-load torque. The Ruths steam-accumular was too large to be shown *en bloc*, but illustrations and plant parts testified to the value of this type of plant for eliminating the peak-load on boiler-plants, especially in works where large quantities of low-pressure steam are required in process work; the boiler can be worked for the average demand, and the pressure, as well as the temperature, of the steam can be maintained at uniform levels. A 300-gallon aluminium still formed an attractive exhibit, and other interesting exhibits included heat-exchangers, crushing machines, compressors of various types, mixers, electrolytic cells, filters, evaporators, film-dryers, scrubbers, and excellent enamelled cast-iron ware. Constructional materials were shown in abundance, non-corroding metals and alloys being particularly conspicuous. Acid-resisting, long-fibred asbestos from the Transvaal, silica-ware, and 'Prodorite,' the new pitch-cement, were among the more noticeable non-metallic resistant materials. No fewer than forty firms were represented at the exhibition, which left a most favourable impression of the quality and diversity of British chemical plant.

ALL interested in technology from whatever point of view will welcome the news that Italy has fallen into line with others of the leading countries of the world, and has commenced the printing *in extenso* and in separate numbers of the specifications of patented inventions. All patents granted after October 1 of last year are, we understand, to come under the new regulation, but it may be hoped that perhaps some day the earlier period will be similarly dealt with so that the record may be complete. The gap is not so large. The old Kingdom of Sardinia printed the specifications and drawings of patents granted under the basic law of 1855 in a publication entitled *Descrizione delle macchine*, which appeared in semi-annual volumes until 1864, when it was replaced by the *Bollettino Industriale del Regno d' Italia*, which continued except for a short period until 1806. Since the latter year, however, those concerned have had to be content with classified lists of inventions from which only the meagre information supplied by the bare titles is obtainable. The new regime is to be congratulated on the revival of the original practice in the more modern style adopted by so many patent offices. Belgium, Spain, and Portugal are the chief European countries that still have to take this step.

AN unofficial committee of twelve members of various points of view, and no doubt of divergent opinions, on economic problems, has drawn up a report which, under the title of "The Facts of Industry," has been published by Messrs. Macmillan and Co. Ltd., (price 1s.). The committee included among others Lord Astor, Prof. Bowley, Mr. W. L. Hichens, Mr. W. T. Layton, Mr. Kenneth Lee, Mr. B. Seebohm Rowntree, Mr. F. Hodges, Mr. A. Pugh, Mr. J. T. Brownlie, and Mr. J. J. Mallon. In other words, it represented employers, employees, professional economists, and trade union officials. The purpose of the committee was to investigate the possibilities of increased statistical publicity, and to ascertain what statistical information is required and how it can be obtained. The committee, agreeing that it is impossible to formulate a wise policy in industrial problems without knowing the facts of the case, has drawn up a series of recommendations, not with the aim of introducing changes in industrial relations, but in the hope of obtaining an adequate basis of facts

on which to discuss any problem that may arise. In problems of industrial relations, information additional to that which is already available should be collected on total production, cost of material and cost of labour. For the study of industrial fluctuations, figures should be provided by each industry as regards stocks, deliveries, and orders on hand. From the point of view of the investor a number of recommendations are also made. The pamphlet indicates reforms which are outside the scope of political controversy, many that have already been put into effect in the United States and none that could fail to throw light on the difficult problems of the day.

DURING the last twenty years the electric pressures used for testing the material and apparatus used by electricians have been steadily rising. Owing to the much wider areas over which power is transmitted, and the greatly increased demand for it, economical considerations make it necessary to increase the pressure. The pressure required in the test room has to be at least double the working pressure. This necessitates the use of very large transformers which need to be housed in special laboratories. A paper on high voltage laboratories by Mr. A. P. M. Fleming, which has appeared in *World Power* for July, is therefore a timely one. Mr. Fleming points out that in order to keep ahead of developments it is necessary that facilities for producing a million volts should be provided. Several million-volt transformers are in daily use in the United States and on the Continent At the National Physical Laboratory the high-pressure laboratory has been built but the apparatus has not yet been constructed. The Soviet Government at Moscow has similar plant under consideration. With these high-pressure transformers, it is very difficult to avoid producing brush discharges and this renders the measurement of the applied pressure very difficult Mr. Fleming points out that the sphere-gap method of measurement is the one that is almost universally used. In our opinion the radiations from brush discharges must seriously affect the pressure at which the disruptive discharge ensues and so must make the readings very uncertain. It is scarcely fair to say that the method is dependent on purely empirical data. One of the data is the value of the maximum potential gradient between the spherical electrodes and the other is purely experimental. The first is computed by advanced theory, the second is got from concordant experimental results obtained in almost every laboratory in the world. For many tests, high voltage direct current is necessary. This is readily obtained by rectifying high voltage alternating current by a thermionic valve rectifier.

THE First Report of the commission appointed to further the study of solar and terrestrial relationships (Étienne Chiron: Paris, 1926), has recently been circulated by the International Research Council, setting out the statements and recommendations made by the committee which met in Brussels last July. Statements are given (1) of the principal terrestrial phenomena definitely known to be affected by intrinsic changes in the state of the sun or by the sun's rotation, such as (*a*) the magnetic state of the earth and earth currents; (*b*) auroræ; (*c*) meteorological and climatic changes; (2) terrestrial phenomena not improbably affected by solar changes but requiring further investigation to establish a definite relationship, such as (*d*) atmospheric electricity (potential gradient and general ionisation of the atmosphere); (*e*) radio-telegraphic transmission; and (3) terrestrial phenomena likely to be affected by solar changes and therefore requiring investigation from this point of view, such as (*f*) the amount of ozone in the upper air; (*g*) the extra-polar auroral light; (*h*) high-level atmospheric absorption; (*i*) penetrating radiation in the atmosphere; (*j*) the light of the night sky. The recommendations of the committee are then given, indicating clearly the particular matters requiring research and co-operation in observation. Memoranda contributed by members of the committee (C. G. Abbot, G. Abetti, S. Chapman, C. Chree, H. Deslandres, G. Ferrié, G. C. Simpson, C. E. St. John, and C. Størmer) and by a few other investigators make an admirable commentary on the foregoing recommendations. The report concludes with a comprehensive summary of literature up to 1924 dealing with the relations of solar and meteorological phenomena. A French version of the complete report is appended.

ABOUT eighteen years ago, Lippmann indicated the possibility of the preparation of a photographic plate that should contain in itself the image-forming elements, and by a single exposure, etc., give a result that would show a picture of the original in stereoscopic relief, adopting the principle of an insect's multiple eye, and Dr. E. Estanave shortly afterwards deposited a sealed communication with the Paris Academy. Dr. Estanave has only recently been able to demonstrate experimentally the possibility of the process, and he describes his method in *La Nature* of June 26, p. 409. The attempt to make it commercially practical by moulding the glass plate so that it shall have one side covered with small, regularly placed, spherically curved projections the principal focal points of which lie on the other surface, which is coated with a fine-grain gelatine emulsion, appears to have failed because the small lenses so obtained were not good enough. The demonstration that the principle is correct was done by making a block of closely packed Stanhope lenses of about 6 mm. focal length each with a square base of about 2 mm. × 2 mm. A photographic plate was placed with its film side in contact with the surface made by the bases of these small lenses, the exposure made and developed, etc., and the plate then attached to the block of lenses exactly in its original position. The composite plate is viewed by looking through it (as a transparency) with the lens surface towards the eyes. The picture of the original object is then seen in stereoscopic relief.

A REPORT issued by the Smithsonian Institution states that news has been received from Dr. Matthew

W. Sterling that the expedition to New Guinea of which he is the leader has started up the Memberamo River. This expedition, which is a joint undertaking of the United States and the Dutch East India Government, is very completely equipped, and has with it an aeroplane for scouting, exploration and cartography. Including carriers and Indonesian troops, the expedition numbers nearly four hundred individuals. Its purpose is the exploration and mapping of the country which lies between the coast line and the range of mountains which forms the backbone of Dutch New Guinea. The members of the expedition are Dr. Sterling, leader and anthropologist, R. H. Peck, photographer, Hans R. Hoyte, chief pilot, A. E. Hamer, assistant photographer and mechanic, S. A. Hadberg, historian of the expedition. Dr. Van Leeuwen, botanist, and M. Leroux, cartographer and surveyor. It is hoped to secure an extensive collection of bird skins in addition to the scientific data for which provision is made in the personnel of the expedition. A special effort will be made to obtain information concerning the pygmy people of the forests on the mountain slopes, of whom comparatively little is known. It is possible that unknown peoples may be discovered in the interior, of whom the existence is at present only suspected.

BEFORE the War the wood-distillation industry in what is now the eastern part of Czechoslovakia was in a very flourishing condition on account of the abundant supplies of beech-wood But the industry has received a severe set-back on account of the rapid development of improved industrial processes for producing both acetic acid and methyl alcohol synthetically. Acetic acid is now manufactured from acetylene by oxidation with oxygen in the presence of vanadium pentoxide and mercuric sulphate as catalysts. More recently methyl alcohol has been made from water-gas, and it is stated in the *Chemiker Zeitung* that the new process may ultimately lead to the abandonment of the older process, although the synthetic product is much less suitable than wood-spirit for the denaturation of fermented spirit The success of the method depends upon the careful control of external conditions, namely, temperature, pressure, nature of the catalyst, and the relative masses of the reacting gases, since methane, carbon dioxide, and water may be obtained as by-products if conditions are not well adjusted. The water-gas needs to be carefully freed from certain impurities, particularly from sulphur compounds.

UNDER the rather curious title of *The Cancer Review*, the British Empire Cancer Campaign has begun to issue a journal of abstracts of the voluminous literature of cancer in its various aspects. The mass of matter printed on the subject of malignant disease is so great and its quality so varied that some such critical collation is most desirable, and we do not doubt that the present journal will be useful. We hope, however, that it will be possible to arrange and group the material more effectively and to supplement the arid abstracts with the critical surveys which may more properly be called 'reviews,' and in these connexions we would commend the admirable *Tropical Diseases Bulletin* to the consideration of Dr. Francis Cavers and his editorial committee. The form is not so good as the substance: it is printed on heavy art paper (illustrations may be contemplated, but there are none in this first issue), and the line is too long (4⅝ inches) for convenient rapid reading—a point on which publishers and physiologists might collaborate with advantage.

A MEETING of the Society for Experimental Biology was held at Edinburgh University on July 17-19. A variety of papers was presented, including one on the growth of fish by Mr. J. Gray, the anterior pituitary and metamorphosis by Mr. E. A. Spaul, the fertilisation membrane of Echinus by Mr. A. D. Hobson, the kinetics of hæmolytic and bacteriolytic reactions by Dr. Ponder, and a demonstration of new methods for studying early stages of cell injury by Dr. Rettie. At a session held in the Botanical Gardens, Dr. K. Blackburn discussed the relation of plant chromosomes to sex, Dr. Philip Smith the effect of acidity on regeneration in Coleus, while Prof. Priestley considered the conceptions of stimulus-transmission and hormones in plants. One session was devoted to a visit to Dr. Crew's laboratory, where breeding experiments with many domestic animals were demonstrated and discussed This was followed by a dinner which was well attended. The next conference will be held in London in December

THE Report of the Director-General of Public Health, New South Wales, for the year 1924, recently received, contains details of the public health administration of the State and of investigations carried out for the Board of Health. In industrial hygiene an investigation has been made of the sandstone dust hazard among miners, quarrymen, and stonemasons It is recommended that a standard of not more than 200 dust particles per c c of air, as determined by the Owens' dust counter, should be adopted for the air of the workings, a figure which can easily be attained by proper methods and ventilation. No cases of plague occurred among human beings or rats. Of the latter, 16,351 were examined, and the species and number of fleas upon the rodents are recorded. Interesting details are given of cases of snake-bite and of paralysis following the bite of ticks.

A NUMBER of scientific expeditions to Arctic Russia and Siberia are announced in the *Weekly News Bulletin* of the U.S S R Society of Cultural Relations, No. 22, vol. 3. The Hydrographical Board has begun the exploration of Maligena Strait which separates Byeli Island from the north of the Yamal peninsula, on the northern sea route to Siberia. Another expedition has left Perm to study the flora and fauna of the Kara Sea, the Ob estuary and the Gulf of Taz. A third expedition, based on Muzhinskoe on the River Ob, is to study the northern Urals, particularly the valleys of the Sosva and Lyapin. Lastly, a geological examination of the coal and oil deposits of northern Sakhalien is promised.

THE Library of the Chemical Society will be closed for stocktaking from Monday, August 2, until Saturday, August 14, inclusive, and will close each evening at 5 o'clock from August 16 until September 11.

THE following have been elected officers of the Institution of Electrical Engineers for the year 1926–1927: *President*, Dr. W. H. Eccles; *Vice-President*, Colonel T. F. Purves; *Hon. Treasurer*, Lieut.-Col. F. A. Cortez Leigh.

APPLICATIONS are invited by the Dorset Field Club for the Cecil medal and prize of 10*l.* for the best essay on "The Wireless Transmission of Power, its Position and Prospects." The competition is open to persons between the ages of seventeen and thirty-five on May 31, 1927, and either born in Dorset or resident in the county not less than one year between May 1, 1925, and May 1, 1927. Particulars may be obtained from Mr F. H. Haines, Appleslade, Ringwood, Hants.

AT a meeting of the Council of the Royal Society of Arts held last week at Clarence House, H.R.H. the Duke of Connaught, President of the Society, presented the Society's Albert Medal for 1926 to Prof. Paul Sabatier, "in recognition of his distinguished work in science and of the eminent services to industry rendered by his renowned researches in physics and chemistry, which laid the foundation of important industrial processes"

NOTICES have been issued of a class in marine biology to be held at the Millport Marine Biological Station during the fortnight August 17-31. Facilities will be provided for collecting and the examination of living specimens, and those attending will be encouraged to investigate some particular problem. Lectures will be given by the Station staff and others on special subjects. Improved facilities for research workers are now available at Millport Laboratory, following the recent installation of electric plant.

THE following are among the recipients of Civil List pensions recently announced: Mrs Marian Dibdin (125*l*.), in recognition of the scientific work of her husband, the late Mr. W. J. Dibdin; Lady Dorothea Hosie (100*l*.), in recognition of the public, literary, and scientific services rendered by her husband, the late Sir Alexander Hosie; Mrs. Elizabeth Japp (100*l*.), in recognition of the services rendered by her husband, the late Prof. F. R. Japp, to the advancement of organic chemistry and chemical education.

IN our issue of July 24, p. 126, we referred to the retirement of Prof. J. A. Fleming from the chair of electrical engineering in the University of London (University College), which he has occupied with distinction since 1885. In recognition of his services to electrical science it has been decided, by a committee presided over by Mr. A. A. Campbell Swinton, to invite subscriptions for a portrait to be placed in University College, and a replica for Prof. Fleming himself, who wishes to offer it to the Institution of Electrical Engineers. Subscriptions should be sent to Prof. W. C. Clinton, University College, Gower Street, London, W.C.1.

WE have received a copy of Circular 279 of the U.S. Bureau of Standards on the relations between the temperatures, pressures, and densities of gases, prepared by S. F. Pickering of the Bureau. It is the purpose of the circular to explain simple methods of making calculations and solving problems involving the properties of gases. Detailed explanations of the gas laws and equations of state are presented together with a large number of charts, tables of data for various gases, and an extensive bibliography.

Natural History, the journal of the American Museum of Natural History, does much to popularise zoology and keep the public informed of discoveries in natural history as they are revealed by study and by exploration in various lands. Its issue for March-April 1926 (vol. 26, No. 2) is devoted to insects and contains a number of general articles admirably illustrated by coloured and half-tone figures. Among the contributors to this issue are Dr. L. O. Howard, who discusses the great economic waste occasioned by insects; Dr. J. Bequaert, who writes on insects and man in tropical America; and Dr. V. L. Kellogg, who describes the structure and functions of the wing-scales of butterflies.

THE British Museum (Natural History), South Kensington, London, S.W.7, has recently issued a fourth edition of the "Guide to the Exhibited Series of Insects" (price 1*s*.). It is a reprint of the previous edition except that a few slight alterations and corrections in the text have been made. Some idea of the magnitude of the main collection of insects that is contained in the Museum may be gathered from the fact that it is now estimated at 3,500,000 specimens comprised in about 250,000 named species. Only a very small representative series of these is exhibited in the public galleries, but the exhibit is sufficiently complete to give the public a general idea of the classification, forms, and habits of all the chief groups of these animals. The present guide serves as a useful brochure on the subject, and should be used by all who wish to make intelligent use of the specimens that are displayed for their benefit in the galleries. It is fully illustrated, and can be obtained either at the Museum or through booksellers.

THE latest catalogue (No. 484) of Mr. F. Edwards, 83A High Street, Marylebone, W.1, will be interesting to those on the look-out for books relating to the Far East, seeing that it gives particulars of many works on China, Formosa, the Indian Archipelago, Japan, Korea, and the Philippines.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A small live-stock instructress and an assistant for general agricultural instruction and dairying under the Surrey Agricultural Committee—C. R. Harding, County

Agricultural Officer and Secretary to the Agricultural Committee, County Hall Annexe, Kingston-on-Thames (August 4). Inspectors under the Ministry of Agriculture and Fisheries for the purposes of the Diseases of Animals Acts 1894–1925—The Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1 (August 9). A lecturer in agriculture at the Agricultural Institute, Plumpton—The Director of Agriculture, County Hall, Lewes (August 10). A lecturer in pathology at the Welsh National School of Medicine—The Secretary, University College, Cardiff (August 21). A senior metallurgist under the British Cast Iron Research Association—The Director, 75 New Street, Birmingham (August 27). A reader in physics at King's College, Strand—The Academic Registrar, University of London, South Kensington, S.W.7 (September 17). A male junior assistant under the directorate of explosives research of the Research Department, Woolwich—The Chief Superintendent, Research Department, Woolwich, S.E 18. A taxidermist for Public Museum -Prof. Carr, University College, Nottingham. A physics mistress at the Cowley Girls' School, St. Helens—The Secretary to the Governors, 17 Cotham Street, St. Helens.

Our Astronomical Column.

JULY METEORS.—Mr. W. F. Denning writes: "A few observations were made at Bristol between July 12 and 22, but meteors seemed somewhat scarce. The coming Perseid shower gave evidence of its presence on July 13 and 16, and several rather bright meteors were seen, presumably from radiants near α and ζ in Cygnus These are well-known showers at about $314° + 48°$ and $317° + 31°$ and appear to be pretty regular in their annual returns. On July 16 and 20, meteors were recorded from a shower directed from a point near α Capricorni ($304° - 12°$). A rather fine object, belonging probably to this stream, appeared on July 20, 2^h 25^m G.M.T., moving along a path of about 45° approximately between Jupiter and Mars and towards Mars. This meteor was seen by an assistant, who pointed out the position, but no other observations have as yet come to hand. This shower of Capricornids is one of considerable activity and seems possibly connected with comet 1881V. Its meteors were numerous in 1908 and 1916, but their chief abundance seems to occur a fortnight before the earth's nearest approach to the comet's orbit."

CHANGES IN THE EARTH'S RATE OF ROTATION.—Prof. Newcomb was the first to suggest that the unexplained oscillations in the moon's position might really be changes in the earth's rotation. Support was given to the suggestion by Glauert, Innes, and others, the test being that other rapidly moving bodies should show similar oscillations, agreeing in phase but differing in amplitude proportionally to their motion.

Prof. E W. Brown contributes a paper to the *Proc Nat Acad. of Sciences*, U.S A. (June 1926), on the subject. He strongly supports the hypothesis, finding, *inter alia*, confirmation from the observations of the sun: there has been a marked deviation from the tables since 1900, which now amounts to 1″ He considers that an oscillation in the earth's radius appears to be the only way of producing such changes in the rotation. Such oscillations were already postulated by Joly ("The Surface of the Earth"), but these are of much longer period than those required for the present research. The chief unexplained lunar term has a period of some 2½ centuries, found by Prof. Turner to be about the same as a period indicated by Chinese earthquakes. The amount of oscillation in the radius required by Brown lies between 5 inches and 12 feet according to the depth of the source, which he estimates to be at least 80 kilometres.

MUTUAL ECLIPSES OF JUPITER'S SATELLITES.—Once in six years the orbit planes of Jupiter's satellites are turned edgewise to the sun, and mutual eclipses of one satellite by another occur. These phenomena have very seldom been observed, for they last so short a time that, unless notice is given beforehand, they are likely to escape detection. The Computing Section of the British Astronomical Association has now undertaken the computation of these phenomena, and gives lists of them for June, July, and August in the March and April issues of its journal. Unfortunately, after July 6, none is visible in England until Aug. 4, when III. is eclipsed by II. at 21^h 28^m. Mr. B. M. Peek described at the June meeting of the Association his observations of three of these phenomena. On June 17, I. was partially eclipsed by II.; at mid eclipse their magnitude was equal, I having been ½ mag. brighter before eclipse. On June 23, III. was eclipsed by II., the loss of light being very appreciable, so that III. became equal to II. On June 28 there was an annular eclipse of II. by I., of very brief duration, since the motion of the satellites was in opposite directions. Fading began at 23^h 46^m 15^s, centrality occurred 23^h 46^m 45^s, and II. suddenly brightened at 23^h 47^m 10^s.

THE REFLECTION EFFECT IN ECLIPSING VARIABLES.—In some cases of eclipsing binaries the light is not constant during the period between two eclipses, owing to reflection of the brighter star's light by the secondary. The hemispheres of the fainter stars facing and remote from the primary are of unequal luminosity and produce a well-recognised effect on the light curve of the system. The theory of this reflection effect is discussed by Eddington in the *Monthly Notices, Roy. Ast. Soc.*, vol. 86, p. 320 (March 1926). He considers primarily the case of the reflection of heat energy, which is greatly simplified by the fact that the 'heat albedo' 1 (*i.e.* a star re-emits completely the radiation falling on it). The phenomenon considered in the theoretical case is not strictly one of reflection, but of absorption and re-emission of radiation, and the conclusions obtained are translated into terms of light reflection by means of simple assumptions. It is shown that the 'reflection' coefficient for heat will not be greater than that for light, and calculated theoretical values are compared with observed values of the reflection effect, in the case of systems of known orbits. Good agreement is shown between the calculated heat reflection and the observed light reflection in seven systems out of twelve, and (contrary to expectation) in only one case is the light reflection the greater of the two. The assumption that the incident radiation is re-emitted in amalgamation with the natural radiation of the fainter star as black body radiation would imply a large increase of the luminous efficiency of this star. The absence of this effect in observed systems suggests that the incident light retains its original quality after 'reflection.'

SANATORIUM TREATMENT OF PULMONARY TUBERCULOSIS.—"Although it was at one time believed that sanatoria were effective in curing phthisis, and at the present time it is tacitly assumed that they are at least effective in favourably influencing the progress of the disease, it has never been satisfactorily proved that such is really the case." With the assistance of M. Noel Karn, Dr. Percy Stocks has made an elaborate study of the first 2794 consecutive cases of undoubted pulmonary tuberculosis brought under the survey of the Belfast Tuberculosis Dispensaries from 1914 onwards. His results, published in *Annals of Eugenics*, vol. 1, parts 3 and 4, show that the average ultimate progress, as estimated over a period of six years unless the patient had been previously lost to view, was undoubtedly worse in the case of the sanatorium-treated than in the case of patients otherwise treated, for cases first seen in the incipient stage, but was not significantly different for patients first seen in advanced stages. Judged by the proportion in whom the disease became arrested or apparently cured, sanatorium treatment showed a temporary superiority during the first two or three years which was lost in subsequent years. While length of stay at a sanatorium was not found to be correlated with ultimate progress, there was an appreciable relation between regularity of dispensary treatment and progress. No consistent evidence was found that bad housing conditions, as judged by rent, class of house, state or cleanliness of rooms, or overcrowding, had any influence on ultimate progress or rate of recovery. The authors suggest that sanatorium treatment should be reserved for patients diagnosed *very early*, those so ill as to require hospital treatment, or those whose circumstances demand their removal from home.

LOUISIANA MOUND BUILDERS.—Dr. J Walter Fewkes, Bureau of American Ethnology, has been engaged during last winter in excavating on the Red River mounds near Marchville, Louisiana, which are, it would appear, of an origin entirely obscure. Breastworks two-thirds of a mile long and 20 mounds, of which the largest, flat on top, is 12 feet high and covers 3 acres of ground, suggest a population of some considerable size. Yet the archæological evidence which has been obtained by excavation suggests a culture of low standard precariously existing in an unfavourable environment. The structure of the mounds varies considerably from that of the Mississippi tribes, Natchez, Choctaw, and others east of the river, or of the Caddo, to the west The mounds appear to be older than those of the Mississippi Valley, and contain no evidence of contact with the white man. They are very poor in artefacts, and it is clear that the living afforded by the area was precarious and meagre. The larger of the mounds contains remains of many skeletons. There are 8 lodge-sights, circular excavations supported by a low embankment. When settlers first visited the country the site of the mounds was occupied by a small tribe of Avoyelle Indians

LUMINESCENCE IN EARTHWORMS.—G. E. Gates (*Records Indian Mus.*, vol. 27, part 6) has observed that four species of earthworms which occur in Rangoon eject from the dorsal pores, after mechanical or chemical stimulation (*e.g.* weak ammonia solution), a mucoid substance which is luminous in various degrees according to the species of worm from which it has issued. The light is not immediately forthcoming on the discharge of the mucus, but appears after a short interval and gradually increases to a maximum. The earthworms are respectively three species of Eutyphœus and one species of Megascolex; no species of either genus has hitherto been reported as luminous.

THE PREVENTION OF DAMAGE BY TERMITES.—Termites or 'white ants' are among the most destructive pests in tropical and subtropical countries. They are well known in these lands to cause serious injuries to woodwork and foundations of buildings, and to furniture and other manufactured articles, as well as injuring trees, crops, and other vegetation. At one time it was believed that the life of a termite colony was dependent upon the presence of the greatly enlarged queen individual, and if she were destroyed, the community would be quickly exterminated. We now know that in the event of her destruction, the life and reproduction of the colony is maintained by other types of queens which, although showing little increase in size, make up in fecundity by their numbers. In *Farmers' Bulletin*, No. 1472 of the U.S. Department of Agriculture, Dr. T. E. Snyder has provided a useful brochure dealing with combating these insects. He recommends that the foundation of buildings should be made of stone, brick, or concrete, including stone or metal columns in the basement to support the floor above. Walls and flooring in basements or cellars should be of concrete, and in no case should untreated timbers be sunk into the ground Where timber is the only practicable material, it should be first impregnated with coal-tar creosote. Complete dryness of foundations of basement flooring is an important means for rendering buildings safe from attack. Many details referring to termite attacks under various conditions will be found in this bulletin, together with recommendations concerning their elimination from cultivated lands

GENETICS OF THE SWEET PEA.—The sweet pea, *Lathyrus odoratus*, was one of the earliest objects of genetical study in the beginning of the neo-Mendelian period. The first case of what is now known as linkage and crossing-over was described in this material As the genetical work with this plant proceeds, the number of linkage groups of characters is still, in the work of Punnett, fluctuating about the haploid number (7) of chromosomes. Partial studies of the pollen development have been made, but the first thorough cytological investigation has recently been published by Miss J. Latter (*Annals of Botany*, April 1926). Several discoveries of much interest are recorded; no more critical paper has appeared in cytology for several years. During the thread stages of meiosis in the pollen mother cell, a definite dark-staining body is discovered in the nucleolus, and it is shown to be invariably connected with a loop of the spireme It grows in size and apparently serves to pass elaborated material from the nucleolus on to the thread There is some evidence that it is derived from a crystalline body which is constantly present in the nucleolus at an earlier stage. The spireme thread shows a telosynaptic history, which is traced with great accuracy. Finally, seven loops are formed radiating from the centre of the nucleus. This is the stage which Gates has called brochonema. During this stage the two arms of each loop, representing a pair of chromosomes, are frequently twisted about each other, thus providing a possible basis for

Fuels," Dr. Ormandy and Mr. D. Ross dealt with the use of alcohol as a motor fuel when mixed with petrol or benzol. Alcohol has the great advantage that it allows the use of a much higher compression ratio in the engine than petrol or any constituent of petrol, thereby obviating premature detonation ('pinking'). Commercial (95 per cent. vol.) alcohol does not mix well with petrol, but now that alcohol can be easily and economically dehydrated by distilling azeotropic mixtures, this difficulty has disappeared. Road tests carried out by the London General Omnibus Co. using petrol with a small proportion of 99 per cent. alcohol, and a mixture of 65 per cent. denatured alcohol, 30 per cent. benzol, and 5 per cent. ether gave quite satisfactory results and showed that, owing to its anti-detonating action, alcohol can advantageously be added to low-grade petrols to improve their value.

The great importance of the size of particles of pigment and compounding powders used in the paint and rubber industries, was discussed at a conference presided over by Sir William Bragg. After Dr. D. F. Twiss and Mr. C. A. Klein had outlined the main problems, specialised papers were read by Dr. S. S Pickles, Dr. P. Schidrowitz, Mr. T. R. Dawson, Mr. Nöel Heaton, Mr. E. A. Murphy, Mr. H. Green (U.S.A.), and by Messrs. G. Gallie and B. D. Porritt. At the concluding sessions Mr. L. J. Simon and Prof. J. W. Hinchley contributed a paper on fat-extraction by solvents, in which they described a new large-scale process for extracting fat from seeds which involves a very short period of extraction, economy in the consumption of solvent, and low capital cost; and Dr. E. W. Smith presented a very useful summary of recent discussions concerning solid smokeless fuel Low-temperature processes, said the author, are at present both technically and economically unproven and the immediate problem consists in improving high-temperature coke for industrial and domestic uses. Such coke must be dry, and contain as low an ash-content as is compatible with economic production. It must be suitably graded, and the grades standardised.

The attendance at all the conferences was very good, and the papers were of a high standard, although there were so many of them that little time was left for discussion Considered as a whole, the meeting was remarkable not only for its magnitude, but also for the diversity and interest of the subjects discussed.

The Commercial Production of Hormones.

AT a joint meeting of the Biochemical Society and the London Section of the Society of Chemical Industry on July 20, a series of papers on "The Scientific and Industrial Problems presented by the Hormones—the Natural Drugs of the Body," was read. The chair was taken by Sir Alfred Mond, who, in the course of his introductory remarks, referred to the work done by the British school on this subject and to the success which has followed the co-operation of the biochemist, the manufacturer and the physiologist, especially in the commercial production of insulin. The financier, though doubtless an essential member of the team, should occupy a subsidiary position to the research worker. Dr. H. H. Dale followed with a paper on the experimental study and use of hormones; Dr. H. W. Dudley described the chemistry of the pituitary gland and of insulin, and Mr. F. H. Carr the commercial production of hormones; Dr H. A. D. Jowett gave an account of the history of adrenaline, and Prof G. Barger discussed the recent progress in the chemistry of thyroxine. Dr. J. W. Trevan's paper on the biological assay of hormones was not read, but in the following account of the main parts brought out by the various speakers, use has been made of an abstract with which we have been furnished.

Only one of the hormones has, so far, been synthesised in the laboratory. Although the presence of a pressor principle in the suprarenal gland was first shown by Oliver and Schafer in 1894, it was not until 1901 that it was obtained in the crystalline state by Takamine, who, with greater courage than was shown by previous investigators, added strong ammonia in excess to the purified aqueous extract of the gland and so precipitated the base. In the same year Aldrich assigned it the formula $C_9H_{13}O_3N$, and this was afterwards confirmed: its structure was definitely proved by Jowett in 1904, who, by exhaustive methylation and subsequent oxidation, obtained veratric acid and trimethylamine, and about the same time the compound was also synthesised by Stolz. The synthetic product was of course the racemic form: in 1908 Flacher separated the dextro- from the lævo- variety, by treating the bitartrate with methyl alcohol, which dissolves the former and leaves the latter behind. The pressor effect of the lævo- naturally occurring form is fifteen times greater than that of its isomer

Although the chemist may have finished with adrenaline, to the biochemist and physiologist it is still the central figure in many unsolved problems. How does the body make it? What is its function under ordinary conditions of life? To the first question there is as yet no answer: to the second a tentative reply may be given, but it is a curious fact that, although adrenaline has so simple a chemical constitution, and such a powerful physiological action when injected, yet its presence in the body under ordinary conditions, except in the suprarenal glands themselves, has been extremely difficult to demonstrate satisfactorily; in fact it has even been denied that it has any function in ordinary circumstances. It is probable, however, that it plays a part in the maintenance of the tone of the small blood-vessels, and also is secreted into the blood stream in larger quantities under conditions of emotional and physical stress.

It is interesting to contrast with the history of adrenaline that of thyroxine. The administration of thyroid gland in myxœdema was the first example of a successful substitution therapy: it is still the main example of this type of treatment, and, excepting possibly the oxytocic principle of the pituitary gland, the only example of a successful result being obtained by administration by the mouth. It is stated to have been used in China for this purpose more than a thousand years ago. But the active principle was not isolated until a few years since, when Kendall was successful in preparing it. Within the last year Harington has been able to synthesise desiodo-thyroxine, the compound formed when the iodine is removed from the molecule of thyroxine. An account of Harington's work has been recently given in these columns (July 10, p. 65), so that it will not be further discussed here: it may be assumed that the final synthesis is now only a matter of time.

The commercial production of other hormones, of which the chemical constitution is unknown, requires the supervision of skilled chemists in the process of manufacture, and the co-operation of the research biochemist in the improvement of existing processes

or the discovery of new ones; the physiologist is also required, since the detection of the presence of the hormone and its quantitative estimation require the use of animal tests in the absence of satisfactory chemical reactions. The usefulness of this co-operation has never been more successfully shown than in the commercial production of insulin. At the present time firms in Great Britain satisfy all home requirements, and have a large balance available for export, whilst the price is low enough to bring the remedy within the means of the poorest diabetic. Of the hormones of, at present, unknown chemical constitution, insulin and those of the posterior lobe of the pituitary gland are the best known. Secretin, the hormone which arouses the secretion of pancreatic juice at the inflow of the partially digested food from the stomach into the duodenum, from the mucous membrane of which it is absorbed into the blood stream, has been recently obtained in a very pure form by J. Mellanby. The active principle of the parathyroid glands and the œstrus-producing hormone of the ovary have been extracted and partially purified, and methods of biological assay, which are probably roughly quantitative, worked out. Of the active principles of the testes, the cortex of the suprarenal glands and the anterior lobe of the pituitary, almost nothing is known; but our ignorance is not due to their non-essentiality, since both the suprarenal cortex and the anterior pituitary are essential to life, whilst an inkling of their functions has been obtained from human and experimental pathology.

An insight into the manufacturing problems is given by a knowledge of the properties of these hormones; insulin and the pituitary hormones may serve as a basis for the following short description. It is probable that the active principles exist in the glands in a combined form, from which they are set free by appropriate treatment; this is certainly the case with thyroxine and probably also with adrenaline. Under certain conditions the hormones will even stand boiling, but, apart from this, their main characteristic is their exceeding sensitiveness to even quite mild reagents. They are rapidly destroyed by autolysis after the death of the animal, being attacked by proteolytic enzymes, though to varying degrees.

This is also probably the reason why the majority are inactive when taken by the mouth, except in relatively enormous doses. They are extremely sensitive to alkalies, but are stable in the presence of weak acids. They appear to be either themselves simple proteins such as an albumose or polypeptide or are closely associated with them. They adhere tenaciously to precipitates formed in their aqueous solutions. Thus Dudley obtained a crystalline picrate from a concentrated aqueous solution of the pituitary hormones, which retained in full its physiological activity when re-crystallised from water; but on re-crystallisation from dilute alcohol, the activity remained behind in the mother liquor, whilst the crystals were identified as potassium creatinine picrate. Abel has recently announced the isolation of a crystalline insulin, the activity of which is two to four times greater than that of ordinary commercial insulin; the crystals bear a remarkable resemblance to cystine. Now it is known that if edestin is allowed to crystallise in a solution of insulin a great part of the activity adheres to the crystals, so that, until further evidence is forthcoming, caution should be exercised in accepting Abel's conclusion.

The principles to be followed in the production of hormones on the large scale must therefore be the inhibition of enzyme action, and the avoidance of the use of destructive reagents or the production of precipitates which remove the activity, except where the latter can be used as a method of purification with recovery of the active principles from the precipitate. The prevention of autolytic changes is best ensured by the freezing of the glands immediately after removal from the animal. The material can then be worked up at leisure and in convenient quantities, though slow changes occur in time in the frozen state, leading to lowered yields. In working up the glands, every means should be taken to prevent enzyme action: thus in the case of the pancreas, the frozen glands are minced, the acid and alcohol incorporated at a temperature of 0° C., and the whole thoroughly ground; filtration and clarification follow to remove, so far as possible, traces of adhering enzymes, and the subsequent concentration is carried out at a low pressure and temperature. In the case of the pituitary gland, dehydration with acetone at a low temperature destroys the autolytic enzymes, leaving a stable powder from which the activity can be extracted by water or dilute acid. The acidity of the solution is of great importance in the case of both insulin and the pituitary hormones. Moreover, use is made of the fact that insulin is insoluble at *p*H of about 5·0 in the later stages of the purification, so that it is essential that those working on the insulin plant should be able to determine the hydrogen ion concentration of the solutions with which they are dealing: a colorimetric method is easy to learn and gives sufficiently accurate information. In the final stages of the preparation of insulin, use is made of Dudley's method, precipitation with picric acid followed by addition of alcoholic hydrochloric acid, by which treatment the insulin hydrochloride is formed and can be precipitated with acetone as a uniform white powder.

In conclusion, reference may be made to one further point in which the co-operation of the manufacturer, the biochemist, and the physiologist may lead to important results. To obtain further insight into the chemical nature of these unknown active principles requires the provision of a moderately large quantity of relatively pure material as the starting point for further analysis. The posterior lobe of the pituitary gland of the ox weighs about 0·5 gm., of which 0·1 gm. is solid matter. Probably less than 0·1 per cent. of this represents the active principles: in other words, to obtain 100 gm. of 'pure' hormone would require the working up of glands from 1,000,000 oxen, with the probability that this material would still be a mixture of active principles and contaminating substances. Large scale working, over a course of years probably, seems the only way to accumulate sufficient material on which the biochemist can commence his research, and until the principles have been isolated in a pure condition, identified and synthesised.

The co-operation of the physiologist will be essential in tracing the course of the hormone through the necessary chemical manipulations. Moreover, until our chemical knowledge of these hormones is complete, quantitative estimation of them can only be carried out by the aid of animal tests. By the use of suitable preparations or a sufficiently large number of animals, the errors in this method of assay can be reduced within reasonable limits: thus for pituitary standardisation (on the virgin guinea-pig's uterus), the error of a single test is ± 20 per cent., and for insulin assay ± 5-10 per cent. Such differences as these would scarcely be detected in clinical medicine, so that the method of biological assay sufficiently safeguards both the physician and the patient.

University and Educational Intelligence.

CAMBRIDGE.—Mr. T. C. Hodson has been appointed reader in ethnology in succession to Dr. A. C. Haddon.

EDINBURGH.—At the graduation ceremonial on July 20, the following, among others, were presented for the honorary degree of Doctor of Laws: The Earl of Crawford and Balcarres, Chancellor of the University of Manchester, a trustee of the British Museum, and president in 1916 of the Board of Agriculture and Fisheries; emeritus Prof. J. S. Nicholson, formerly professor of political economy in the University of Edinburgh; Lord Salvesen, formerly president of the Zoological Society of Scotland and of the Royal Scottish Geographical Society.

The degree of Doctor of Science was conferred on Dr. D. A. W. Fairweather for a thesis on "Electrosynthesis"; Dr. S. R. Khastgir for a thesis on "Studies in the J-transformation of Scattered X-radiation"; Dr. J. Muir for a thesis on "The Flora of Riversdale, South Africa"; Mr. J. D. M'B. Ross for a thesis on "A Relationship between the Associating Power of Optical Isomers, and the Formation of Racemic Compounds"; Dr. G. Shearer for a thesis on "The Application of the Method of X-ray Analysis to the Study of the Organic Aliphatic Series."

At the medical graduation ceremonial on July 23, intimation was made of the award of the Cameron Prize in practical therapeutics to Dr. H. H. Dale, head of the Department of Biochemistry and Pharmacology under the Medical Research Council, for important investigations on the pharmacological and therapeutic action of a series of substances which have effects on the functional activity of nerve, muscle, ductless glands, and other tissues.

LEEDS.—Mr. A. E. Ingham, Fellow of Trinity College, Cambridge, has been appointed reader in mathematical analysis in succession to Dr. W. E. H. Berwick. Mr. Leonard R. Johnson has been appointed assistant lecturer in agricultural zoology.

LONDON.—Mr. E. B. Verney has been appointed as from August 1 to the University chair of pharmacology tenable at University College. Mr. Verney was educated at Tonbridge School, and at Downing College, Cambridge. He was assistant in the Department of Physiology at University College from 1921 until 1924, and since 1924 has been assistant in the Medical Unit at University College Hospital. In July 1922 he was awarded a Beit Memorial Fellowship and was re-elected for a 4th year in 1925.

Mr. S. J. Davies has been appointed as from August 1 to the University readership in mechanical engineering tenable at King's College. He was educated at H.M. Dockyard School and the Technical College, Portsmouth. Since 1920, Mr. Davies has been senior lecturer in engineering at Armstrong College, Newcastle-upon-Tyne; he has also lectured at the Technische Hochschule in Charlottenburg and in Düsseldorf and Essen.

The title of emeritus professor of electrical engineering in the University has been conferred on Prof. J. A. Fleming, on his retirement from the University chair of electrical engineering at University College.

THE honorary degree of D.Sc. of the University of Wales has been conferred on Sir T. W. Edgworth David, professor of geology in the University of Sydney, for distinction as a geologist and his eminent position in the university life of Australia; and on Dr. A. H. Church, University lecturer in botany, Oxford, for his distinguished contributions to botanical science.

NOTICE is given by the Huddersfield Technical College of the forthcoming award of the two following research scholarships, each of which is of the yearly value of 100*l.*, with remission of fees: The Joseph Blamires' (for research in colour chemistry), and the Drapers' Company's (tenable in the dyeing department). Particulars of the scholarships are obtainable from the principal of the college.

THE College Research Committee of Armstrong College, Newcastle-upon-Tyne, has recently initiated a new scheme under the title of Senior Research Fellowship. A member of the staff elected to a fellowship is released from teaching duties for one year, the Research Committee providing the salary of a temporary lecturer from the funds at its disposal. A first appointment has been made of Dr. G. R. Goldsbrough, lecturer in applied mathematics.

THE Trustees of the Beit Fellowships for Scientific Research at their annual meeting extended the fellowship awarded a year ago to Mr. Rudolf Kingslake for mathematical and experimental researches on the properties of optical instruments. Three new fellows were elected: Mr. J. Topping for research on the calculation of the equilibrium configuration and energy of crystals from the mutual electrostatic and repulsive forces, in particular Al_2O_3 and Fe_2O_3; further extension of the research upon which he is at present engaged and the calculation of the repulsive forces for the nitrate crystals and further comparisons of calcite and aragonite; Mr. J. W. Maccoll for research in aerodynamics; and Mr. G. H. Mitchell for research on the Borrowdale volcanic rocks of the eastern part of the Lake District, more especially in the Kentmere and Troutbeck areas, in continuance of research now being pursued. For the first time in the history of the Trust, the appointments are for the definite period of two years instead of for one year as hitherto.

THE Education Committee of the London County Council, on the advice of its Consultative Committee on Engineering, has awarded Robert Blair Fellowships to Mr. Malcolm D. Bone and Mr. Eric W. Fell. These fellowships, which are of the value of 450*l.*, are awarded to young engineers of high promise to enable them to undertake research overseas. Mr. Malcolm Bone, who is a student-assistant with the Consett Iron Co., is the son of Prof. W. A. Bone, of the Imperial College of Science and Technology, South Kensington. He was educated at St. Albans Grammar School, Mill Hill School, the Friends' School, Sidcot, and the Imperial College. He will now study iron and steel manufacture in continental works, mainly in Germany. Mr. Eric Fell is a research student in the University of Birmingham who was previously educated at St. Aubyns School and Haileybury. Like Mr. Bone, he also proposes to study in Germany and to undertake research in the metallurgy of steel at the Technische Hochschule, Aachen. Four Robert Blair Fellowships have already been awarded for research in the United States, Canada, and in Germany. The first research report written as the result of these awards has recently been received from Mr. George Bird, who gained a fellowship two years ago. This report has been forwarded to the Institution of Mechanical Engineers, with the result that Mr. Bird has now been invited to write a paper, dealing with some particular phase of his investigations, for publication in the proceedings of the Institution.

Contemporary Birthdays.

July 28, 1864. Prof. Charles Herbert Lees, F.R.S.
July 30, 1856. Viscount Haldane, K.T., O.M., F.R.S.
Aug. 2, 1876. Prof. James Wesley Jobling.
Aug. 5, 1878. Prof. Louis C. Karpinski.
Aug. 7, 1864. Mr. Oswald H. Latter
Aug. 8, 1845. Mr. William Barlow, F.R.S.
Aug. 8, 1859. Sir Alfred G. Bourne, K.C.I.E., F.R.S.
Aug. 8, 1857. Prof. Henry Fairfield Osborn, For Mem. R.S (see page 163).
Aug. 8, 1858. Sir Francis G. Ogilvie.

Prof. LEES, who occupies the chair of physics in the University of London (East London College), was born at Glodwick, Oldham. He was educated privately, then at Owens College, Manchester, and at the University of Strasbourg. Before engaging in professional work in London he was lecturer in physics in the University of Manchester.

Lord HALDANE, Chancellor of the University of Bristol since 1909, was educated at Edinburgh Academy, the University of Edinburgh (of which he was rector, 1905-8), and at Göttingen. He is Hon. D.C.L. (Oxon). Among many critical expositions, he is the author of "The Philosophy of Humanism" (1922). Lord Haldane is president of the British Institute of Adult Education.

Prof. J. WESLEY JOBLING was born in Ohio. Originally on the teaching staff of Columbia University, he was professor of pathology from 1914 until 1918 in the medical department of Vanderbilt University, Nashville (Tennessee), returning then to Columbia to occupy the chair of pathology there

Prof. LOUIS C KARPINSKI, mathematician, was born at Rochester, N Y. He was educated at the State Normal and Training School, Oswego, N.Y., and the University of Strasbourg Since 1910 he has been professor of mathematics in the University of Michigan He is joint author with H Y. Benedict and J. W. Calhoun of "Unified Mathematics" (1918).

Mr OSWALD LATTER, who has been for many years science master at Charterhouse School, was born at Fulham. From Charterhouse he went to Keble College, Oxford Sometime Berkeley fellow of Owens College, Manchester, he was also a tutor of Keble before returning to his old school to take up science teaching

Mr. WILLIAM BARLOW is a Londoner. He is specially identified with researches on crystal structure and related problems. Mr. Barlow is a past president of the Mineralogical Society.

Sir ALFRED BOURNE, a native of Lowestoft, was educated at University College School, London. His services to the Indian Empire have been varied and distinctive. Successively he has been registrar of the University of Madras, botanist to the Madras Government, and professor of biology in the Presidency College, Madras.

Sir FRANCIS OGILVIE, an Aberdonian, graduated at the University of Aberdeen, and, early in his career, was on its teaching staff. In Edinburgh he had, later, various important interests. He was principal of the Heriot-Watt College there from 1886 until 1900, thereafter, for three years, director of the Edinburgh Museum of Science and Art. Transferred to London, he was Secretary of the Board of Education for the Science Museum and Geological Survey from 1910 until 1920, holding also the directorship of the Science Museum. Sir Francis was principal assistant-secretary, Department of Scientific and Industrial Research, 1920-22. He is Hon. LL.D., Edinburgh.

Societies and Academies.

DUBLIN

Royal Irish Academy, June 28.—**H. Ryan, J Keane**, and **B. O'Donoghue**: Some derivatives of γ-piperonylidene-methylethylketone. The present communication describes the results of experiments carried out with this substance and some aromatic aldehydes. The starting substance, $CH_3 . CO . C(CH_3) = CH . C_6H_3 . O_2CH_2$, was prepared by the condensation of piperonal and methylethylketone in the presence of hydrochloric acid. By the action of piperonal on γ-piperonylidene-methylethylketone in the presence of alkali, a compound having the formula $C_{20}H_{16}O_5$ was obtained. This dicondensation derivative did not react with a further quantity of piperonal in the presence of alkali, and it was regarded as being 1-methyl-4·5-dipiperonyl-cyclopenten (3)-one (2). On treating this compound with alcoholic hydrochloric acid, it was converted into the isomeric 1-methyl-4·5-dipiperonyl-cyclopenten (4)-one (2). This substance reacted with piperonal in the presence of alkali to form a tricondensation compound $C_{28}H_{20}O_7$. By the action of piperonal on γ-piperonylidene-methylethylketone or on the $C_{20}H_{16}O_5$ body in the presence of hydrochloric acid, the same tricondensation compound $C_{28}H_{20}O_7$ was obtained. This derivative is regarded as being 3-piperonylidene 1-methyl-4·5-dipiperonyl-cyclopenten (4)-one (2). The results obtained in this research are similar to those found by Ryan and Lennon in their investigation on the condensations of aldehydes with methylethylketone.—**H. Ryan, J. Keane**, and **B O'Donoghue**: Some derivatives of α-piperonylidene-methylethylketone. The results of the interaction of α-piperonylidene-methylethylketone and some aromatic aldehydes are described. By the action of piperonal on the starting substance, a compound having the formula $C_{20}H_{16}O_5$ was obtained. This dicondensation derivative of methylethylketone and piperonal was not identical with either of compounds having the same molecular formula obtained by the action of piperonal on γ-piperonylidene-methylethylketone. The last-mentioned derivatives are regarded as isomeric cyclopentenones. The $C_{20}H_{16}O_5$ body prepared by the action of piperonal on α-piperonylidene-methylethylketone formed a tetrabromide and did not react with a further quantity of piperonal. It is regarded as α-γ-dipiperonylidene-methylethylketone. By the action of piperonal on α-piperonylidene-methylethylketone in the presence of hydrochloric acid, a tricondensation compound $C_{28}H_{20}O_7$ was obtained. This body was also prepared by the action of piperonal on γ-piperonylidene-methylethylketone and was proved to be 3-piperonylidene-1-methyl 4·5-dipiperonyl-cyclopenten (4)-one (2).—**R K. Boylan**: Atmospheric dust and condensation nuclei. As a result of observations made in Dublin between October 1925 and June 1926, using Owens' jet dust counter and Aitken's apparatus, the following average values were obtained: dust particles per c.c. 1580, nuclei per c.c. 23,800. The correlation coefficient between the concentrations of the two bodies was 0·73 · 0·056. It was found, in confirmation of the results of Wigand, that dust particles would not act as centres for cloudy condensation even in the absence of the ordinary nuclei.

EDINBURGH.

Royal Society, July 5.—**J. Tait**: Experiments and observations on Crustacea (Pt vii.). Some structural and physiological features of the valviferous isopod Chiridotea. This isopod is found along the eastern shores of America. It is peculiar among its kind in that it combines the activity of swimming, walking,

and tunnelling in sand, and the position and arrangement of its limbs may be interpreted in relation to each of these purposes as well as in relation to its habits of feeding.—Norman **Maclaren**: Development of Cavia Implantation. The theory put forward by Graf von Spee, that in the guinea-pig the ovum is implanted in the uterine mucosa after the manner of a parasite in virtue of the destructive action of its surface cells, has been generally accepted. An alternative theory for the primary phases of implantation here discussed brings the process in Cavia more into line with what is known to occur in other mammals. Instead of eating its own way through the epithelium, the egg becomes lodged in one of the crypts which normally occur at the antemesometral end of the uterine lumen. This crypt becomes closed by the overgrowth of its lips, while the epithelium which originally formed its floor disappears. With the disappearance of the epithelium, destructive changes supervene in which the whole antemesometral part of the lumen is involved. The primary implantation cavity is thus a part of the uterine lumen, and the process does not, in principle, differ from that which occurs in certain other rodents such as the mouse and rat.—W. L. **Ferrar**: On the cardinal function of interpolation theory. Interpolation over a set of equi-distant points by cardinal function formula is 'consistent,' *i.e.* a function which is given accurately by the interpolation formula applied to the values of the function at points 0, $\pm nw$ is also given accurately if w be replaced by any smaller w'. The formula consists of an infinite series; its relation with a corresponding infinite integral is considered.—E. L. **Ince**: Researches into the characteristic numbers of the Mathieu equation. (Second paper.)

SHEFFIELD

Society of Glass Technology, June 1 and 2.—Sir W. Flinders **Petrie**: Glass in early ages. No glass was made in Egypt prior to about 1500 B.C., all earlier specimens being imported, probably from the Syrians. Examples of glass had been found in Syria, in the Euphrates region, which can definitely be dated back to 2500 B.C. Only fifty years or so elapsed between a time when glass was a comparatively rare commodity in Egypt and a time when it was possibly the commonest commodity of all. Glass vases and glass beads rapidly came into everyday use. At first it was not a liquid glass which was produced, but a glass paste which could be moulded in the plastic state. No blown glass was found in Egypt until one came to an examination of the products of the Christian period. The whole of the earliest glasswares discovered in Egypt were coloured. It was not until about 1200 B.C. that the Egyptians began to make glass by pressing it into moulds, and from thence onwards, until the seventh century B.C., the colour of their glasswares got worse and worse, although the patterns became more and more composite. From the year 350 A.D. the Egyptian glass-makers resorted to the moulding of glass in the production of standard weights for gold coins, a practice which was later copied by the Arabs. The glazing of stones began in Egypt about the twelfth century B.C. Some of the tiles covering the walls of early Egyptian chambers are magnificent examples of colouring; not only single colours were achieved, but also polychromes.—J. W. **Ryde**: Opal glass. A number of commercial and experimental glasses have been examined by the X-ray method in order to determine the nature of the opacifying material which separated out. Sodium fluoride and calcium fluoride had separated out from the glasses examined. The rates of cooling were controlled, and varied so that the effect of the rate of cooling on the depth of opal produced could be investigated. With slow cooling the size of particles which separated out increased until a certain limiting size was reached. In bulbs made of opals in which the opacifying particles are relatively large, very little light is scattered back to traverse the bulb again.—F. F. S. **Bryson**: The electrical conductivity of glasses at high temperatures. The electrical conductivity of several series of glasses was determined at temperatures between the softening point and 1150° C. The glass was heated in a small cylindrical crucible in a platinum wound electric furnace. The temperature-resistance curves for several glasses bear a close relationship to the temperature-viscosity curves for similar glasses, and suggest the possibility of using conductivity measurements as a method of determining changes in the viscosity of a glass immediately before being worked.—Edith M. **Firth**, F. W. **Hodkin**, M. **Parkin** and W. E. S. **Turner**: The influence of moisture on the rate of melting and on the properties of soda-lime glasses. Moisture was present in amounts ranging from 0·25 to 15 per cent. in different batches. In general, when present to the extent of not more than 1-2 per cent. in soda ash batches and not more than 3-4 per cent. in batches containing both soda ash and saltcake, moisture has a beneficial effect on the rate of melting. The glasses which were made from batches containing saltcake, were refined more easily, and were freer from waviness than those prepared from batches containing soda ash only. Glasses prepared from batches containing more than 5-6 per cent. of moisture were more viscous and had a shorter working range than those prepared from ordinary dry batches.

PARIS.

Academy of Sciences, June 21.—A. **Lacroix**: Preliminary note on an aerolith discovered in the Department of the Côte-d'Or and remarks on the classification and nomenclature of the chondrites.—Charles **Richet** and P. **Lassablière**: The protective effects of preliminary saline injections on chloroform anæsthesia. Experiments on dogs have proved that the injection of a solution of common salt into the veins before administering chloroform increases the resisting power of the heart. The amount of chloroform can be increased to six times the normal without collapse.—Gabriel **Bertrand** and M. **Mâchebœuf**: The influence of nickel and cobalt on the action produced by insulin in the rabbit. It has been shown previously that the pancreas is one of the organs containing the largest proportions of nickel and cobalt, and preparations of insulin are even richer in these two metals. This suggested the study of the effect of adding nickel or cobalt or both to preparations of insulin and examining the physiological effect. The effects, which are marked, are shown in a series of graphs.—E. **Bataillon**: The membranogen process and the regular development provoked in virgin eggs of Echinus by hypertonic treatment alone.—Pierre **Weiss** was elected a non-resident member in succession to the late G. Gouy.—A. **Buhl**: The integration of Maurer's equations by series of homogeneous functions.—Armand **Cahen**: Differential equations of the first order linear with respect to the function and the variable.—Renato **Caccioppoli**: Linear functionals.—A. **Tychonoff**: Abstract spaces.—N. **Lusin**: An arithmetical example of a function not forming part of the classification of M. René Baire.—Henri **Bénard**: The inexactitude, for real liquids, of the theoretical laws of Kármán relating to the stability of alternate vortices.—**Garsaux**: The provision of aeroplanes with oxygen. A device is described in which a specially constructed Dewar vessel containing liquid oxygen replaces the usual

cylinder of compressed oxygen: the weight of the apparatus is reduced to one-tenth of that when an oxygen cylinder is carried.—**Dumanois**: The retarded inflammation effect produced by antidetonants. The effect of the addition of such substances as lead tetraethyl to petrol is to retard ignition.—L. **Cagniard**: The use of the quadrant electrometer in high-frequency measurements of precision.—R. **Forrer**: The structure of the atomic magnet. The deformation of the multiplet by the field. The triplet in iron.—F. **Wolfers**: Interferences by diffusion.—R. de **Mallemann**: The dispersion of electrical double refraction of camphor. The specific double refraction of active camphor and of inactive camphor are sensibly identical. The dispersion is normal.—H. **Jedrzejowski**: The method of preparation of sources of RaB + RaC.—Pierre **Achalme** and Jacques **Achalme**: The influence of the viscosity on the specific rotatory power of certain active bodies. Two series of experiments are described, one in which the concentration was kept constant and the viscosity varied by the addition of solution of citric acid, the other in which the viscosity was kept constant and the concentration varied. In the first case the calculated specific rotatory power varied from 13·6 to 6·2; with concentration variable from 3·75 per cent. to 60 per cent. tartaric acid, viscosity constant, the calculated specific rotatory power was practically constant, 8·3 to 8·5. It is pointed out that this new fact of the effect of viscosity is of importance as affecting deductions on the molecular structure of active bodies.—Edmond **Bauer**: The electric structure of the molecules, particularly mesomorph bodies (anisotropic fluids).—P. **Surun**: The adsorption of some organic acids by two activated carbons of different origin. The data given are not in accord with the conclusions of Fromageot and Wurmser, which were based on experiments with Urbain carbon.—F. **Bourion** and E. **Rouyer**: Discussion of the results obtained in the quantitative study of the association of mercuric chloride. Reviewing the work of Linhart, Beckmann, together with the results of their own experiments, the authors conclude that there is equilibrium between simple and double molecules of mercuric chloride at 25° to 40° C. for concentrations not greater than 0·37 mol. There is equilibrium between simple and triple molecules at 100° C. and for concentrations higher than 0·5 mol.—E. **Sterkers** and R. **Bredeau**: Contribution to the study of reactions between solid bodies reduced to the colloidal state. Details of the preparation of calcium resinate in a colloidal mill. Zinc oleate and magnesium stearate can be prepared in a similar manner.—Ch. **Maurain**: The relations between terrestrial magnetic disturbances and solar activity.—Alb. **Frey**: The pigments of *Sterigmatocystis nigra*.—Ph. **Joyet-Lavergne**: The heterogamy of the spores of the horsetail and the characters of sexualisation of the cytoplasm.—R. **Combes** and R. **Echevin**: The variations in the organic matter, mineral matter, and especially calcium, in the leaves of trees during the autumnal yellowing.—H. **Prophète**: Contribution to the study of the waxes of flowers: rose wax. The results of a detailed chemical examination are given.—E. **Chemin**: The development of the spores of *Colaconema Bonnemaisoniae*.—Mme. L. **Randoine** and R. **Lecoq**: Do the water soluble vitamins (B) contained in beer yeast exist beforehand in the culture medium? It has been shown in an earlier communication that beer yeast and extracts of beer yeast, so far as concerns the water-soluble vitamins, have a higher value than that of other Saccharomyces or of other yeast extracts of different origin. It is now shown that the source of these vitamins is the malt extract used as the culture medium.—Jules **Amar**: Cellular pigments and physico-chemical actions.—Maurice **Piettre**: Some physical and chemical influences in hæmolysis by hæmolytic immunoserums.—J. **Benoit**: Differentiations, spontaneous and provoked, in the genital glands of the Gallinaceæ.—René **Fabre**: A spectrophotometric method for the study of hæmolysis.—L. **Mercier** and Raymond **Poisson**: Parasitic microsporidia of Mysis.—Edm. **Plantureux**: An antirabies vaccine containing formaldehyde.

CAPE TOWN.

Royal Society of South Africa, April 21.—C. von **Bonde**: The chorology of the S. African Heterosomata with some relative problems. The zoogeographical distribution of the S. African flat-fishes is dealt with. Part I. deals with ecology or environment of the species, and Part II. with chorology or their distribution in space. A comparison of the distribution of the Heterosomata with that of other marine faunas shows a remarkable agreement in the ratio of their occurrence in deep sea or in shallow water, the number of endemic species and the preponderance of east coast species.—A. **Ogg**: The structure of the sulphates.—W. A. **Humphrey**: (1) An occurrence of diamonds near Port Nolloth. This occurrence is the first to be discovered on the coastal belt south of the Orange River. The gravel is disposed in alternating layers of loose gravel and thin partings of hard conglomerate in which the constituents of the gravel are cemented together by a calcareous cement. This points to a seasonal deposition of gravel by a stream which was intermittent in its flow. The gravel shows signs of long-continued transport and the diamonds also show slight traces of wear. The source of the diamonds is probably somewhere within the basin of the Kammas River, with which the watercourse containing the gravel was once connected. The diamonds are very brilliant, white and well crystallised. (2) The changed conditions of Namaqualand. The river valleys of Little Bushmanland immediately south of the Orange River have been formed by the action of streams of considerable volume, which cut their way through masses of mountains during some far-distant pluvial period. The upper courses of the shorter tributaries of the Orange in this neighbourhood have been gradually filled up with drift sand which has encroached from the north and obliterated the stream valleys altogether; in some cases mountain ranges are in the process of being buried. The climate has changed from one with a comparatively heavy rainfall to its present semi-arid character. Similarly the Kammas River now no longer carries water to the sea, but is in course of filling up its own bed by its summer floods, which now spread the detritus from the Klipfontein Mountains in wide alluvial flats. This portion of Namaqualand represents an exceedingly old land surface in which valleys are gradually being filled up owing to a decrease in the humidity of the climate.—R. C. **McGaffin** and E. **Newbery**: Single potential of the copper electrode. Very varied results have been obtained by different workers for the single potential of copper in solutions of its salts. One, at least, of the main factors producing this variation is the formation of an insoluble film of basic salt by the action of the electrolyte upon the metallic copper. Attempts have been made to obtain concordant and trustworthy values (*a*) by careful cleaning of the electrode and measurement of the potential immediately after immersion, and (*b*) by retarding or if possible, preventing the formation of the film either by rapid rotation of the electrode or by violent stirring of the electrolyte.

Official Publications Received.

Journal of the College of Agriculture, Hokkaido Imperial University, Sapporo, Japan. Vol. 16, Part 1: (i) Über die qualitativen Methoden zur Methylpentosanbestimmung, von Kintaro Oshima und Kinsuke Kondo; (ii) Über die quantitative Bestimmung von Pentosan und Methylpentosan, von Kintaro Oshima und Kinsuke Kondo. Diary of Societies.

AUGUST 4 TO 11.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (at Oxford).

Wednesday, August 4 (in Sheldonian Theatre), at 8.30 P.M.—H.R.H. The Prince of Wales: Presidential Address.

Thursday, August 5.—At 10 A.M.—Addresses by Sectional Presidents: B.- Prof. J. F. Thorpe, F.R.S.: The Scope of Organic Chemistry.—C. —Prof. S. H. Reynolds: Progress in the Study of the Lower Carboniferous (Avonian) Rocks of England and Wales.—F. —Sir Josiah Stamp: Inheritance as an Economic Factor.—K —Prof. F O. Bower. 1860-1894-1926.

At 11 A.M.—Addresses by Sectional Presidents: E. Hon. W. Ormsby-Gore: The Economic Development of Africa and its effect on the Native Population.—I.—Prof J. B. Leathes: Function and Design.—Discussion (Section M): Cultivation Methods.

At 2.—Conference of Delegates of Corresponding Societies.—Sir John Russell: Regional Survey (Presidential Address).

At 2.15.—Dr. F. A. Dixey: Recent Criticisms of the Theory of Mimicry (Lecture).

At 2.30.—Discussion (Sections E, H): The Effect on African Native Races of Contact with European Civilisation.—Discussion (Section M): Soil Classification.

At 5.—Discussion: (Sections L, M): Educational Training for Overseas Life.

Friday, August 6.- At 10 A.M.—Addresses by Sectional Presidents: G.—Sir John Snell: The Present and Future Development of Electricity Supply—L.—Sir Thomas Holland. Discussion (Section C). Problems of the Thames Gravels.—Discussion (Section M). Agricultural Education.

At 11 A.M.—Discussion (Section L): Scholarships.

At 11.30 A.M.—Addresses by Sectional Presidents: D.—Prof. J. Graham Kerr: Biology and the Training of the Citizen.—J.—Dr J. Drever: Psychological Aspects of our Penal System.—Discussion (Section K): Sex Determination in Plants.

At 2.30.—Discussion (Section I): The Relationship of Vitamin B to Bios.—Discussion (Section L): The Cinema in Education.

At 3-15.—Discussion (Section I): The Meaning of the Symptoms of Beri-beri.

At 3-30.—Discussion (Section L): Wireless in Education.

At 8.—Prof. A. S. Eddington: Stars and Atoms (Evening Discourse).

Monday, August 9.—At 10 A.M.—Addresses by Sectional Presidents: A. —Prof. A. Fowler. The Analysis of Spectra.—H.—Prof. H. J. Fleure: The Regional Balance of Racial Evolution.—M.—Sir Daniel Hall: The Limits of Agricultural Expansion.—Discussion (Section B): Tautomerism.—Discussion (Section L). Recent Advances in Educational Science.

At 11 A.M.—Discussion (Section K): Vegetative Propagation.—Discussion (Section D): The Training of a Zoologist.

At 2.—Discussion (Sections D, H, J): Heredity in its Physical and Mental Aspects.

At 8.—Prof. H. F. Osborn: Discoveries in the Gobi Desert by the American Museum Expeditions (Evening Discourse).

Tuesday, August 10.—At 10 A.M.—Prof. J. S. Huxley. The Study of Growth and its bearings upon Morphology (Lecture).—Discussion (Section L). The Public School System.

At 11 A.M.—Discussion (Sections C, D, K): The Conception of a Species.

At 11.30 A.M.—Discussion (Section M): The Feeding of the Dairy Cow.

At 12 noon.—(Section I) by Dr. J. S. Haldane: Acclimatisation to High Altitudes (Lecture).

At 2.—Conference of Delegates of Corresponding Societies.

At 2.30.—(Section J) by Miss W. Spielman: Recent Progress in Vocational Selection (Lecture).

At 5.—Sir F. Keeble: The Nervous System of Plants (Lecture).

Wednesday, August 11.—At 11 A.M.—Discussion (Section E): Regional Work in Geography.

At 12 noon.—Concluding General Meeting.

SATURDAY, AUGUST 7, 1926.

CONTENTS.

The State and Science.

IN electing the Heir to the Throne to fill its highest office, the British Association has honoured both science and itself. Since the Prince Consort filled this position in 1859, no member of the Royal Family has presided at its functions, and in succeeding his great-grandfather, H.R.H. the Prince of Wales has followed worthily in the footsteps of one who revealed an extraordinary insight into the possibilities of science, and initiated proposals that have led not only to the wide dissemination of scientific knowledge, but also to the harmonious co-operation of Science and the State.

The British Association has long been regarded as the mother of scientific parliaments, among the most important duties of which is that of bringing home to our people the significance and value of science to human life. No more effective spokesman could have been chosen than His Royal Highness, who, by virtue of his great experience as a traveller and interest in world-affairs, and of his immense popularity among all classes of the population, is pre-eminently qualified to convey the message of science to the nation and to the Empire. The onlooker, he says, sees a great deal of the game, and his experiences of things military and naval, his contacts with industry, education, public health, land-settlement, agriculture, transport, and housing, have convinced him that the future of civilisation lies "along a road of which the foundations have been laid by scientific thought and research." He has also come to realise that the future solution of practically all our industrial and social difficulties will only be found by scientific methods.

However divergent men's views may be on the course of human progress, whether it is rectilinear, or gyratory with frequent interruptions (like the recent traffic in Piccadilly Circus), the most pessimistic will admit that the thoughts, interests and achievements of men have appreciably expanded within modern times, and that this development has been attended by a noticeable growth in the spirit of toleration. Our universities are now open to all classes, creeds, and nationalities; the social 'cat' can not only look at the social 'king,' but rub shoulders with him on the playing field and at charitable functions; we no longer consign to the stake those who practise the profession of necromancy, or to the gallows those who unlawfully prey upon their fellow-citizens: instead, we give them 'space' in our popular newspapers, and leave them to the verdict of 'time.' This unfolding of the spirit of toleration is especially marked in the attitude of conservative interests towards science, and the Prince is very happy in his allusion to the Oxford Meeting of the British Association in 1832, when there was strong opposition

to conferring honorary degrees on such distinguished men of science as Brewster, Robert Brown, Dalton, and Faraday, whom Keble stigmatised as a "hodge-podge of philosophers"; and in his reference to the memorable meeting in 1860 when Bishop Wilberforce, at his famous encounter with Huxley, displayed an attitude of mind toward science that is rarely found nowadays, although, as Tennessee has taught us, it is not yet quite extinct. Such times are happily past, and even our most ancient and orthodox institutions are doing their best to march to the syncopated strains of modern civilisation. We must not, however, forget that feeling of 'dumb hostility' toward science and its works, referred to by Prof. Lamb in his presidential address last year, and again by the Prince on the present occasion; or the even more blighting feeling of apathy which still stalks in the land. Both these negative forces are the consequences of that ignorance and lack of imagination which instigated Voltaire to remark that although we had a hundred different religions, we had only one way of cooking a potato.

The history of the relations between science and the State in Great Britain, which is one of the principal themes of the presidential address, was sketched with a masterly hand, and nothing in it is more remarkable than the long period of delay—more than eighty years—which elapsed between the conception of a State department of science and its realisation when the Department of Scientific and Industrial Research was established during the late War. The time-lag between thinking and doing is ascribed by the Prince to lack of prevision of successive Governments, and to mutual distrust between science and the State; to these causes we would add ignorance of science and its methods, and the conservative attitude of the governing classes toward any disciplines which might compete with the study of the humanities and with orthodox religion. Many of us can well remember the bitter controversies which took place during the latter part of the last century between the respective champions of individualism and collectivism, and whilst the contention of the former that the genius of our people is ill-adapted to wholesale measures of nationalisation or widespread State control, is still held by the majority, it is evident that the ultra-individualism advocated by J. S. Mill, Herbert Spencer, and others is equally unsuitable as a practical creed. At any rate, time has largely solved the problem by the parliamentary method of compromise, and if we are not 'all socialists now,' we recognise that in certain matters affecting the welfare, and even the existence of our people, there is a legitimate field of State intervention; not necessarily for the purpose of assuming control, but rather for that of rendering assistance and giving advice.

Opinions will, of course, vary concerning the nature and extent of the fields into which the State can usefully penetrate. Those leaders of modern thought who are not obsessed by the mechanical and material aspects of Western civilisation, conceive progress to lie in a sense of values, and the majority of them admit that the cultivation of science, the broad and imaginative outlook which that cultivation engenders, and the application of scientific discoveries to human ends, are among the things that really matter to-day. Security in time of war, industrial progress in time of peace, education and national health at all times, cannot be left entirely to individual effort and initiative; and the only question that arises is the nature and range of the help which the State should give. In this connexion, the views recently expressed by the Earl of Balfour to the Society of Chemical Industry, which are evidently the views of the Department of Scientific and Industrial Research, over which he presides, are of interest. Apart from allocating grants to universities and the Royal Society, Lord Balfour holds that the State should not concern itself directly with promoting or assisting fundamental research work. Nor should it travel to the other end of the scale by finding capital for building factories and acquiring markets. Its legitimate sphere lies in helping to bridge the gap between laboratory experimentation and full-scale industrial operation, and in maintaining institutions like the National Physical Laboratory and the Fuel Research Station which, among other duties, pursue investigations of fundamental problems that are common to many industries, and therefore of great national importance.

In the recent attitude of the State toward science, the Prince discerns "a definite step in human progress," which is both novel and teeming with possibilities for Great Britain, the Empire, and the relations subsisting between them. Few, if any, of us know as much about the conditions in, and the needs of, our great overseas dominions as does the Prince; and none can speak with greater prestige. His remarks on the importance of extending knowledge of our overseas territories, on the value of co-ordinating the results of research work throughout the Empire, and on the good that results from personal contact between scientific workers from its various parts, require no emphasis from us; but we would point out that much as men of science may strive to serve the needs of Empire in the manner indicated, their services can only be small compared with those rendered by H.M. the King and H.R.H. the Prince of Wales, who, by their repeated visits to the Dominions, have strengthened beyond measure the natural ties of kinship that attach the motherland to her children beyond the seas.

Bacteriophage.

The Bacteriophage and its Behaviour. By Dr. F. d'Herelle. Translated by Dr. George H. Smith. Pp. xiv+629. (Baltimore, Md.: Williams and Wilkins Co.; London: Baillière, Tindall and Cox, 1926.) 36s. net.

AN indication of the appeal that the subject of bacteriophage has made to the interest of bacteriologists is afforded by the fact that, in this second book of d'Herelle's, the bibliography contains more than six hundred papers, of which more than five hundred have appeared during the last five years. In taking up the book one has in mind not only the importance of the bacteriophage in relation to fundamental problems of bacteriology, but also that the author was the first to make extensive investigations on the subject, under this name, and to demonstrate the phenomena by the striking and easily learnt technique which made it at once widely known. From the beginning of his publications in 1917, he has maintained the view that the bacteriophage is a living nonvisible virus that exists as a parasite upon bacteria. All the facts discovered since that time have been interpreted by him on the basis of this hypothesis and, as was to have been expected, it is in the light of this interpretation that the book has been written.

All those who have worked at the bacteriophage are not, however, adherents to this view. The phenomena produced by the bacteriophage and such properties of the active principle (bacteriophage itself) as can be determined by controlled experiments, are generally accepted. But to many the significance of these facts is chiefly in their relation to the possibilities afforded for further investigation of the nature and causes of bacterial variation and further analysis of bacterial metabolism. To these fields bacteriophage has opened new and valuable approaches, none the less valuable because numerous scientific investigators are unable to accept the hypothesis of a living virus. Amongst other contributions to the discussion written with less advocacy of a particular point of view, those of Bordet (*Annales de l'Institut Pasteur*, 1925, 39, 717) and Otto and Munter (*Ergebnisse d. Hyg., Bakteriol., Immunitätsforsch., u. exp. Therapie*, 1923, 6, 1) may be noted. The book under discussion is more than a review of the subject, it is as well an argumentative exposition of the author's views of the nature of the bacteriophage, his interpretation of the phenomena produced by it and his claim to priority in its discovery.

The larger part of the introduction of thirty-four pages is taken up with mention of observations of others so far back as 1892, in which, in the light of present knowledge, bacteriophage may have played a part. In several instances it is impossible to be certain whether this is a correct surmise, but it appears highly probable that the irregular forms of colonies described by Gildemeister (1917) in cultures of *B. typhosus* and *B. coli* were the result of the action of bacteriophage. Gildemeister himself is of this opinion. Five pages are occupied with a detailed consideration of a paper by Twort (1915) which appeared two years before d'Herelle's first publication and of which he was at that time unaware. The contention is that the phenomena described by Twort were not due to bacteriophage, although this view is not held by most of those who have studied the question and written on it. Indeed, though the class of bacteria was different and the ease of demonstration was less, it is generally accepted that the main characters of the two phenomena are identical and that Twort recognised the essential facts though uncertain as to the interpretation. The point in continuing these arguments for priority is not clear. It seems quite certain that d'Herelle was not the first to observe the phenomena due to the action of what we now term 'bacteriophage,' but, on the other hand, no one wishes to detract from the work of d'Herelle, who was the first to make extensive systematic investigations in the subject, and was chiefly responsible for bringing it forcibly to the attention of the scientific world.

The book itself is divided into three parts: (1) The phenomenon of bacteriophagy, (2) the bacteriophage, (3) the behaviour of the bacteriophage protobe. A lengthy discussion of these matters would lead one into highly technical fields of bacteriology into which it is not possible to enter here or necessary for those who are acquainted with the subject. For those who may wish to inquire further, d'Herelle's book or the reviews that have been mentioned will be of value.

In general terms the phenomenon of bacteriophagy consists of bacterial lysis transmissible in series. If one puts a small amount of 'bacteriophage' with a culture of a susceptible bacterium in a liquid medium, in the course of a few hours the turbidity of the culture decreases. Not all the bacteria are destroyed, however, and from the lysed culture, subcultures can be obtained of bacteria that resist lysis when exposed again in a similar way to bacteriophage. If the lysed culture be filtered through a Chamberland or similar filter, and all the bacteria removed, the filtrate contains a much greater amount of bacteriophage than was originally put in; the increase may be as much as ten thousand times in the course of six or eight hours. This process can be repeated indefinitely, the bacteriophage increasing in association with living susceptible bacteria upon which it has a lytic action. A similar lytic phenomenon may be obtained on solid media if

inoculation is made with a mixture of bacteriophage and susceptible bacteria. In place of normal bacterial growth there will develop, according to the conditions of the experiment, small clear areas devoid of growth, larger irregular areas, or almost complete absence of growth. If inoculation be made sparsely to allow isolated colonies of bacteria to be seen, some of them will be deformed by the absence of growth in part of the area they would normally have covered.

The bacteriophage is therefore an 'agent' or 'principle' that passes readily through filters that retain bacteria, that increases in association with living bacteria which are susceptible to lysis by it; its action upon a susceptible culture shows that all the organisms in the culture are not equally susceptible but that some are resistant, and if isolated are neither lysed by bacteriophage nor permit its increase in association with them.

The bacteriophage was first obtained by d'Herelle from the intestinal contents of patients recovering from dysentery. A Chamberland candle filtrate of a culture of intestinal contents added to a culture of a suitable organism produced clearing of the turbidity. Since then bacteriophage has been found widely distributed. It is present in the intestinal contents of healthy individuals and animals, in purulent discharges, in sewage, in river water, in soil, etc. In discussing the "ubiquity of the bacteriophage," p. 37, one would like to have seen set down along with these other sources the experiments of Bordet, who obtained bacteriophage from the exudate that formed after guineapigs were inoculated intraperitoneally with *B. coli.* One notes also that the experiments of Otto and Munter, who found that bacteriophage appeared spontaneously in some of the cultures in their laboratory, are dismissed with brevity. It is a question of fundamental importance whether the phenomena associated with bacteriophage are accentuations of processes that normally occur in bacteria. To dismiss these experiments with the statement that the strains from which bacteriophage had been directly derived had been "contaminated" with it from the time of their isolation, that is, that the bacteria and the bacteriophage virus had been isolated together from the body is, to say the least, a one-sided account and is, in fact, begging the question.

The explanations given of the phenomena of bacteriophagy are all based on the author's view that the bacteriophage is composed of individual living 'corpuscles.' For example, the mechanism of dissolution of a bacterial cell by bacteriophage as seen by the author under dark-ground illumination is summed up in a paragraph on p. 115, ". . . the single fact that the phenomenon of rupture is 'explosive' in nature shows that the bacteriophage corpuscle certainly penetrates to the interior of the bacterium, and that it is in this location that multiplication takes place." It is stated without any qualifications in the context, p. 18, that "the science of immunity has been held back for more than twenty years by the equivocation created in the subject by the term 'lysis,' which as a matter of fact has entirely lost its real significance." For this reason the destruction of the bacterial cell by bacteriophage is termed 'dissolution.'

One notes also the manner of mentioning the work of others whose results have been difficult to assimilate into the author's thesis. In particular, a sentence on p. 212, referring to one whose work is well known and accepted, which reads: "the contribution is absolutely incomprehensible, and it would seem that he has no idea of what in reality is the phenomenon of bacteriophagy," is an illustration of the author's attitude of mind.

The second part of the book deals with the characters of the bacteriophage itself. Its behaviour towards physical and chemical agents is discussed and a chapter is devoted to hypotheses concerning its nature, in which this aspect of the subject is extensively presented.

A point of some interest is the introduction of a new term to indicate a class or genus which is to include several of the so-called filterable viruses. The definition is as follows (p. 359):

"Up to the present time the infravisible agents of rabies, of variola, of vaccinia, of encephalitis lethargica, of the animal plagues and of the mosaics of plants, have been considered by the majority of biologists as living beings, but this point of view has been, however, disputed. Although the proof of the living nature of the bacteriophage is only valid for itself alone, it is none the less true that the living nature of all the beings which present the same characteristics is rendered the more probable by the facts disclosed in connexion with the bacteriophage. These infravisible beings have been termed 'invisible viruses,' 'ultraviruses,' 'ultramicrobes,' etc. This does not give them a name, for these terms are simply qualifying terms, designating their state of invisibility. In presenting the demonstration of the living nature of the bacteriophage I have proposed to designate this group of living 'micellar' beings by the name Protobes, a term which I have applied to the bacteriophage."

P. 357: "It is to this being, infravisible, parasite of bacteria, that I have given the name *Protobios bacteriophagus* (syn. *Bacteriophagum intestinale*) d'Herelle 1918."

The rôle of the bacteriophage in immunity is, broadly, the subject of the third part of the book. On p. 488 is found, "With plants, as with animals, antibacterial immunity is 'exogenous,' it is the bacterio-

phage protobe. This is a general fact throughout nature." If this were so one might expect important results from prophylactic immunisation with bacteriophage and its use in treatment. The final two chapters are taken up with these matters, but the enthusiasm of the author for his theme has produced an atmosphere of hope which will require much further work to be justified. Whatever view may be taken of the nature of the bacteriophage, it has undoubtedly a markedly destructive action on susceptible bacteria in the test-tube, but the principles involved in employing bacteriophage for prophylaxis or treatment of disease are as yet but little understood, and indeed further evidence is required to establish the reality of this branch of therapeutics.

The book, compared with the first one "Le bactériophage, son rôle dans l'immunité," 1921 (English translation, 1922), has increased in size. The presentation of almost every aspect of the subject has been expanded. A section on ultra-filtration is new. Much of the discussion concerning the various hypotheses that have been put forward to explain the nature of the bacteriophage is also new. This part of the subject has been given attention by most of those who have worked at bacteriophage. One is dealing with a filtrable, non-visible agent, possessing unique properties, of much interest in its relation, on one hand, to living viruses, and on the other, to bacterial and cellular lysins and to enzymes. In spite of much work, this exact relationship is still undetermined.

The Science of Photography.

(1) *The History of Three-Color Photography.* By E. J. Wall. Pp. x+747. (Boston, Mass.: American Photographic Publishing Co., 1925.) 15 dollars net.
(2) *Stereoscopic Photography: its Application to Science, Industry and Education.* By Arthur W. Judge. Pp. xv+240. (London: Chapman and Hall, Ltd., 1926.) 15*s.* net.
(3) *Die photographisch-chemische Industrie: die Erzeugung und Verarbeitung photographisch-chemischer Präparate.* (Technische Fortschrittsberichte, Fortschritte der chem. Technologie in Einzeldarstellungen, Band 10.) Pp. xvi+363. (Dresden und Leipzig: Theodor Steinkopff, 1926.) 18·50 gold marks.

PHOTOGRAPHY, in common with some other subjects, has the peculiarity of being both an art and a science. The manufacture of sensitive emulsions suitable for very variable requirements, the design of cameras and optical systems by the use of which the light impression is obtained on the sensitive film, and the processes of development, printing, etc., are essentially scientific, involving as they do chemical and physical problems which are often of a very complicated nature. On the other hand, photography is commonly spoken of as an art, and it may be said that, with few exceptions, the best exponents of the art know very little of the science underlying the use and practice thereof. Even in connexion with the scientific side, it is true to say that the present high standard which has been reached in the manufacture of plates, films, and papers, which may be used for an infinite variety of purposes and in all climes, is due to empiricism and experience having far outstripped scientific knowledge; this is also true of developers and development, toning, sensitising and de-sensitising dyes, etc. At the same time, it must be emphasised that since the investigation of the scientific foundations of photography was initiated by Hurter and Driffield, increasing attention has been paid to this branch of applied science, and the effect of the results obtained has been very marked on the progress of manufacture and on the applications of photography.

In two of the branches of photography dealt with by the works under review, namely, colour photography and stereoscopic photography, it is self-evident that the scientific basis is all-important, and that any advances made must be dependent on progress made in our knowledge of colour and stereoscopy. At the same time, the necessity of satisfying artistic requirements has had a great influence in directing the course of scientific inquiry. The third book, "Die Photographisch-chemische Industrie," treats only of matters which are industrial and scientific in character.

(1) Mr. Wall has long been noted for his encyclopædic knowledge of the processes of photography, especially of colour photography, and it is not to be wondered at that he has produced a remarkable and unique book. It is the product of thirty years' study and search of the original literature of colour photography and allied subjects, and the author claims, with justification, that "there is no work in any language which has brought together a history and summary of colour photography comparable to this book." Reserving the Lippmann, Seebeck, and bleach-out processes and photo-mechanical reproduction for another volume, the attempt is made to record, even to the most minute detail, every step in the progress of colour photography of both still and moving subjects, from the earliest beginnings to the early part of 1925; detailed references to the original articles or patent specifications are given in every case. The first chapter gives the necessary "Historical and Theoretical Data," after which comes an extremely valuable chapter on colour filters and colour screens,

the use, preparation, and transmission factors of which are given in detail. In three succeeding chapters, still cameras and chromoscopes, bi-packs and tri-packs, and various optical devices are described. Colour sensitive plates, with the methods of sensitising and testing, de-sensitisation, and the preparation of photographic papers, are fully discussed and a list of sensitising dyes, together with their range of action, is given. Subtractive processes and screen plates are dealt with, each in five chapters, whilst other chapters give an account of three-colour transparencies, autochrome stereoscopy, dichromate printing, prismatic dispersion processes, etc. The chapter on colour kinematography is most valuable; this has necessitated a search of the patents of all countries, there being practically no literature on the subject.

The great value of this book lies in the fact that the practising photographer, the inventor, and the researcher will find therein complete records of what others have done; time will not be wasted in re-discovering ideas already known. In this respect it should be mentioned that numerous patents are reviewed which could not be found from the patent office indexes, as they are listed only under other classifications.

Very few errors and misprints have been noticed, but occasionally, as on pp. 55 and 544, the author's mathematical equations go wrong, although the right result is obtained in the end. It is stated that the edition is limited and the type will be distributed as soon as printing is completed, otherwise the reviewer would have suggested that the various and numerous data which are given in terms of the Fraunhofer lines should be expressed in wave-lengths in the next edition.

(2) On the Continent, stereoscopic photography seems to be practised much more than in England, and, for the most part, the literature has been chiefly in French and German. The appearance of an English book on the subject is therefore to be welcomed, not only because stereoscopic photography forms a fascinating hobby, but also because of the applications to which it is being put. The anaglyph is being utilised more and more for the stereoscopic illustration of commercial catalogues, books, and magazines.

The reader of the book will probably be surprised at the extensive applications of stereoscopy in science.

"By its aid the microscopist, for example, is able to observe stereoscopically and to photograph the minute solid objects revealed under his microscope, and eventually, in the stereo-photographs, to obtain permanent records of these objects in relief. The astronomer employs stereoscopic principles not only to detect the presence of faint stars and binaries, but also to show in realistic relief the features of the moon, comets, certain of the planets, and also the proper positions in space of stars of greater magnitudes forming the constellations. The radiographer is enabled by stereoscopic X-ray pictures to locate exactly foreign bodies in the human system, to show the position of flaws, air-pockets, or defects in castings, metals, or other materials, and to reveal the internal structures of organic bodies and interiors of composite bodies and mechanisms."

It is becoming of increasing importance in aerial and land survey, and its possibilities in enabling the student to visualise complex diagrams and objects are being recognised more and more.

In order to maintain a popular as well as technical interest in stereoscopy, the theoretical and analytical sections have been reduced to the minimum proportions, but the treatment is sufficient for the end which the author has in view, namely, that of interesting both the advanced worker and the amateur. Stereoscopy with a single lens camera, the selection of stereoscopic cameras and accessories, the viewing of stereograms, photographic processes, and notes, etc., are all adequately described before the applications of stereoscopy are considered. For those who wish to pursue the subject there is an appendix giving a bibliography of the literature. There is no lack of illustrations, there being some 150 line and half-tone reproductions and 19 plates in stereoscopic pairs.

The author is to be congratulated on a book which will occupy a worthy position in English photographic literature.

(3) This book, as its title indicates, is mainly concerned with the manufacture of photographic material, and gives a literature summary covering the period from 1914 to the present time. There are four sections, which deal respectively with: (*a*) The manufacture and testing of photographic dry plates, (*b*) the manufacture and testing of films, (*c*) the manufacture and testing of photographic papers, and (*d*) the working of photographic materials. This last section occupies practically half of the book and deals with the testing of photographic materials and the usual operations of photography (exposure, development, etc.). Fundamental researches on the scientific basis of photography are not neglected, but are not dealt with in detail. The German aptitude for summarising literature is well in evidence, and if this book is used together with the various Reports on Photography which have been published by the Society of Chemical Industry, it will be invaluable to photographic workers, both those in the industry and in research laboratories.

There are occasional errors, and among these the names of English workers sometimes suffer considerably, as when "Fog" is written for "Toy."

T. S. P.

History and Evolution.

Theory of History. By Prof. Frederick J. Teggart. (Published on the Foundation established in Memory of Philip Hamilton McMillan of the Class of 1894, Yale College.) Pp. xix+231. (New Haven, Conn.: Yale University Press; London: Oxford University Press, 1925.) 14*s*. net.

PROF. TEGGART'S book is a useful and learned contribution to a very important contemporary discussion. What is the relation between historical method and the method in the natural sciences, and especially in that nearest to history, namely, biology? It would be difficult to find any statement so clear and pointed as Prof. Teggart's of the difference that has arisen, mainly in the last century and especially since Darwin, between what one may call the 'sociological' and the 'historical' school among the writers of history. Prof. Teggart states it clearly, truly, and forcibly, and traces it to its source; he gives apt and numerous quotations from representative thinkers; unfortunately, he does not work out his own solution in the same fulness. He points out the difficulties, but does not solve them: the solution, in fact, demands a prolonged and thorough philosophical treatment, far beyond the scope of his short essay, and still more of a shorter notice of it. However, we may be thankful to him for having cleared the ground, and await the more leisured cultivator who must come later.

To take two prominent names as representing the two philosophical poles in the discussion, Comte and Bergson: as Frenchmen they have the national gift of expressing logical extremes, though it would be easy in each case to quote amply from the author evidence that his own practice was not, and could not be, in accord with his own logical presumptions. Comte is fully, and on the whole justly, treated by Prof. Teggart as the most powerful voice in the nineteenth century in favour of the sociological, or generalising, view of history. That view maintains that in the limit, that is, if our knowledge were complete, and in proportion as our knowledge increases, we can formulate 'laws' for history and neglect particular events and personalities; that, in the limit, human history would become, like astronomy, a completely reasonable evolution of an idea, or set of ideas, which with adequate knowledge might always have been predicted beforehand as we predict the movements of the heavenly bodies. That is the extreme, logical or determinist point of view, and it was fortified in 1859 by Darwin's formulation of evolution as proceeding by an infinite and unceasing series of minute variations. Its extreme opposite can be found in M. Bergson's view that every human action is a new and creative thing, and that our actions become more perfectly human just in so far as they are free and undetermined by previous happenings. History, therefore, which is an account of human action, cannot be a science, because it deals with the particular and individual, whereas science is always making general conceptions from the recurrence of particulars. Prof. Teggart illustrates this attitude from the two leading thinkers in the nineteenth century who reacted against the generalising and intellectualist attitude in human affairs—Schopenhauer among philosophers and Ranke among historians. This part of his book is the most impressive.

Where is the plain man to take his stand, especially one who comes to history from the orderly discipline of the natural sciences? He will say, in the first place, that neither of the extreme philosophical points of view can be wholly true; he will deny, on one hand, that every human action or event can be properly treated as merely individual; he will be sure that there are, if not 'laws,' at least connexions, movements, and tendencies in history. On the other hand, he will be equally sure that exact formulation, as in the case of mathematics, or prediction, as in the case of astronomy, is out of the question in history or sociology. He will look in history for general similarities and general movements containing an infinite variety of individual difference and freedom of development. To reconcile this apparent contradiction is one of the greatest and noblest objects of human thought.

Two limited and definite suggestions may be made here, appropriate to Prof. Teggart's book. One is that he makes no allowance for the increasing importance of the history of thought in general history. This is the most characteristic and decisive thing in the history of history-writing in the nineteenth century. Whewell was its first exponent in Great Britain about a hundred years ago, one of the first exponents in the world of the history of science as a whole. This aspect of history has made increasing strides ever since, and has now several organs and a mass of literature in all leading educated communities in the world. Now in so far as we look on the history of scientific thought as a guiding thread in general history, so do we perceive an orderly advance and a community of mankind. Above all, it enables us to take a more decided line on the other and last point on which we will comment on Prof. Teggart. He ends his book by saying that the difficulty which he has been discussing will be largely solved "if we recognise the difference between a ***belief in progress*** and a ***belief in the possibility of progress***." The difference will not appear so great between the two attitudes if we reflect that a belief in the possibility of progress, that is, in the future, depends on the establishment, by history, of progress in the past: and, as

the progress of science is the most obvious and measurable thing in history, those, like Prof. Teggart, who would build their faith on the 'possibility' of progress in general, must turn to the annals of systematic and objective thought. F. S. MARVIN.

Our Bookshelf.

Essex: an Outline Scientific Survey; including Geology, Botany and Zoology. By Members of the Essex Field Club and others. Prepared on the Occasion of the Congress of the South-Eastern Union of Scientific Societies at Colchester. Edited by G. E. Hutchings. Pp. 133+4 plates. (Colchester: Benham and Co., Ltd., 1926.) 3*s.* net.

THIS "Outline Scientific Survey," published in connexion with the recent Congress of the South-Eastern Union of Scientific Societies, at Colchester, should prove of wide and permanent interest. Consisting of a series of articles by well-known field naturalists, it provides a detailed account of past researches into the geology, botany, entomology, ornithology, crustacea, etc., of Essex, summarising the great volume of work accomplished by the Essex Field Club during the forty-six years since the club was founded, and work done by earlier Essex naturalists.

Covering a wide field, the articles are necessarily condensed, and will appeal to scientific workers rather than to the general public. The value of this survey is enhanced by the bibliographical notes appended to each article, and by the geological sketch map of the county. A useful index of the survey is also provided.

Owing to limitations of time and space, omissions could scarcely be avoided. One finds in the survey no mention of the mammals, reptiles, and fishes of Essex. These have been fully dealt with by the late Dr. Laver, past president of the Essex Field Club, in a special memoir published by the Club, and also in a report upon Essex and Kent sea fishes, compiled by the late Mr. E. A. Fitch, also a past president of the Essex Field Club, collaborating with the late Dr. Murie, published by the Essex and Kent Sea Fishery Board. Another special memoir of the Essex Field Club deserved attention, namely, the very complete report upon the Essex earthquake, by Meldola and White; and it is surprising to find no reference to the historic and world-renowned 'native oyster'—a variety of the oyster confined to the estuary of the Thames. The oyster fisheries of Essex have certainly been protected for more than seven centuries, probably for more than a thousand years, and possibly from Roman times. As the partridge and pheasant, similarly protected, are always included in British bird lists, we should have expected the Thames Estuary variety of oyster to figure in a scientific survey of Essex. An exhaustive account of this fishery by a member of the Essex Field Club appears in the Essex "Victoria History," and later a pamphlet was published, compiled by the late Dr. Laver, who took a keen interest in this fishery. The small but interesting pyrites industry formerly on the Essex coast, an account of which (by a member of the Club) is included in the Essex "Victoria History," also deserved mention. These omissions could be remedied, in later editions or reprints of the survey, by a brief editorial note.

Monumenta Medica. Under the General Editorship of Henry E. Sigerist. 3: *The Earliest Printed Literature on Syphilis; being Ten Tractates from the Years 1495–1498.* In complete Facsimile, with an Introduction and other accessory material by Karl Sudhoff, adapted by Charles Singer. Pp. xlviii+352. (London: D. Stanton, 90 North Road, N.6; Florence: R. Lier and Co., 1925.) n.p.

OWING to rearrangements, incorporations, and other changes, this beautifully printed and illustrated work, which forms the third volume in the series of "Monumenta Medica," of which the second was reviewed by us some months previously (NATURE, December 5, 1925, p. 811), is, as Dr. Singer remarks in the preface, almost a new work rather than a translation. The writers whose works are reproduced in facsimile are Konrad Schelling of Heidelberg, physician to Philip, Elector to the Palatinate and friend of the humanist Jakob Wimpheling, Joseph Grünpeck of Burckhausen, himself a sufferer from the disease, Niccolo Leoniceno of Vicenza, whose pamphlet was published by the great humanist printer Aldus Manutius at Venice, Hans Widmann of Tübingen, Caspare Torrella of Valencia, who was physician to Pope Alexander VI. and treated his son Cæsar Borgia for syphilis, Corradino Gilino, who recommended the heroic treatment of application of a red-hot iron to the head for curing the salivation caused by mercurial inunctions, Bartholomæus Steber of Vienna, Natali Montesauro of Verona, the first to describe clearly the ostescopic pains of syphilis, and Antonio Scanaroli of Modena. Their contributions to the history of syphilis, while none of them is without considerable interest, are of very unequal value. With the exception of Grünpeck's pamphlet entitled "Ein Hübscher Tractat von dem Ursprung des bosen Franzos," all the tracts are written in Latin.

Prof. Sudhoff regards the work of Torella entitled "Tractatus cum consiliis contra pudendagram seu morbum gallicum," as the most valuable of all the tracts, inasmuch as it is the least prejudiced, the freshest, and the least academic. Perhaps the next most interesting pamphlet in this collection is that entitled "De pustulis et morbo qui vulgo mal de franzos appellatur" by Hans Widmann, who distinguishes the French disease from leprosy, holds the breath of the sufferers to be contagious, and regards the rashes and, above all, the affection of the mouth, as characteristic of the disease.

As Prof. Sudhoff points out in his foreword, the works reproduced will prove of interest not only to epidemiologists and medical historians, but also to students of the history of culture and the art of printing.

Dialogues in Limbo. By George Santayana. Pp. vii+193. (London: Constable and Co., Ltd., 1925.) 10*s.* 6*d.* net.

THE dialogue form enjoys a mild vogue among American philosophers, and it is hard to imagine any more brilliant exponent of it than Mr. Santayana. It expresses admirably the subtle irony of his delicately perceptive intelligence. Of the literary success of his experiment there is no question. Yet interpretation is hard, for, as in all living discussion, the emphasis shifts

and one cannot certainly infer what the message is. The scene is Limbo. The spirit of the earthbound stranger holds converse with the illustrious shades—Democritus, Aristippus, Alcibiades, Socrates and the rest—who manage to retain a stronger personal identity than even Mr. Broad's 'psychic factor' would explain; and much of their discourse is at variance with the 'Life of Reason.' For there, at all events, Mr. Santayana has declared himself on the side of reason, has shown how, from the raw material of human character, its diversity of impulse and of passion, reason has to create some kind of harmony; but here the issue is less certain.

Of all the shades, Democritus is endowed with the greatest power and energy of conviction; and he, as frank materialist, is clear enough that the life of reason is largely illusion, and that "the chief and most lasting illusion of the mind is the illusion of its own importance." True, the illusion is necessary and in its way beneficent; for the state of wisdom is "an evanescent madness when the dream still continues, but no longer deceives." Even Democritus, however, can scarce tell whether it is more important that the dream should continue or that it should not deceive. On one side, the practical business of life requires its endurance, since only so can we forbear the bewilderment of ultimate inquiry, and like Protagoras take the way of establishing, by the support of tradition and experience, a valid conventional distinction between sane beliefs and mad. Yet, when the deepest challenge comes, Democritus is impelled to the vow, "I will dismiss and expel every remnant of illusion, even in myself, in order that nothing of me may remain save the atoms that compose me"—truth before aught else. So, too, in a not dissimilar ethical discussion, the dialectic of Socrates can overthrow the vaguely emotional democratic theory of the stranger; but makes less headway against the stranger's version of the teaching of his prophet of human love and gentleness.

There is no finality here: no set conclusion, but a lively and sensitive handling of the issues, and a breathless brilliance of fine debate. H. J. W. H.

An Introduction to Historical Geology: with Special Reference to North America. By Prof. William J. Miller. Second edition. Pp. xvi + 399. (London: Chapman and Hall, Ltd., 1925.) 13*s.* 6*d.* net.

PROF. MILLER'S "Introduction to Historical Geology" is not quite so successful as his "Physical Geology," recently reviewed in these columns. The fundamental principles of stratigraphy and the organic inferences are carefully dealt with, and the book contains very useful summaries of Palæozoic and Mesozoic life-forms. Indeed, throughout the book the palæontology is well done. But physical history is especially emphasised, and yet here the treatment follows the conventional lines of older text-books and fails to include the results of much modern work. In dealing with geological time the author is particularly old-fashioned. He writes, "the Cambrian period represents a long time, the best estimates ranging from 2,000,000 to 3,000,000 years. . . . Though the succeeding periods were by no means equal in duration, the best estimates would make no one of them less than 1,000,000 years long." The term 'best' evidently applies to the old estimates of Walcott, and implies ignorance of, or indifference to, the magnificent work of Barrell in this field. More attention might also have been devoted to the palæographical researches of Schuchert, which reveal at least eighteen great marine transgressions over the North American continent. The book is well printed and illustrated, but reveals no originality of either point of view or treatment.

Sahara. By Angus Buchanan. Pp. xv + 301 + 78 plates. (London: John Murray, 1926.) 21*s.* net.

CAPT. BUCHANAN has added to his previous works on Africa another valuable book in which he shows his power of descriptive writing and his insight into the native mind. His journey on this occasion was across the Sahara from Kano by way of Ahaggar to Touggourt and Algiers. The main objects of his journey were to secure kinematograph films and make studies in natural history. Happily he avoids the monotonous iteration of daily marches and incidents of camp life, and succeeds in giving a series of vivid pictures of the Sahara, its animal life and its people. While the interest is mainly in natural history, there is a great deal of geographical value in the book. In fact, few volumes give better impressions of the vastness and solitude of the desert. It is a pity that the small map is wholly inadequate for a book of this importance.

Nature, Thought and Personal Experience. By Dr. W. Tudor Jones. Pp. xii + 182. (London: Williams and Norgate, Ltd., 1926.) 7*s.* 6*d.* net.

DR. TUDOR JONES has consciously or unconsciously come under the influence of the new doctrine which is being preached in science under the descriptive title emergence. The theory of emergent evolution is an attempt to interpret the process of the cosmos as a succession of 'levels,' each level being characterised by new properties which, though the outcome of the conditions of the previous level, could not be predicted from it. With his well-known zeal for the recognition of moral and religious values, Dr. Tudor Jones applies this as a rationale of the relation of Nature and thought in personal experience. Though dealing with values, he never loses touch with the actualities of positive science.

My Flight to the Cape and Back. By Alan J. Cobham. Pp. vi + 70. (London: A. and C. Black, Ltd., 1926.) 1*s.* 6*d.* net.

THIS small volume is a modestly told record of the great achievement of Mr. A. J. Cobham in flying from London to Cape Town and back last year. It was not a hurried flight, as lengthy halts were made at several places on the route via Italy, Greece, Egypt, the Nile, the Lake Plateau and Bulawayo, but it was most successful and singularly free from mishap. The reader may regret the lack of adventure, for Mr. Cobham does not even embroider his story, and makes slight of every incident. But the absence of sensation is a tribute to the skill of the pilot and the worth of his machine. There are several interesting aerial photographs.

Lightning.

IN a recent and very interesting article (*Proc. Roy. Soc.*, A, 111, 56-67, 1926, May 1), Dr. G. C. Simpson advances a theory of the method of advance of a lightning stroke. As he concludes that there can be no substantial stroke of negative charge, perhaps it would be better to say that he develops a theory of the advance of a positive stroke, meaning by this the advance of a stroke of positive charge. A short time ago, I proposed (*Journ. Franklin Inst*, **201**, 485-496, 1926, April) a theory of the advance of a negative stroke. As the two theories are apparently conflicting, it is desirable to consider the conflict in order to see in how far it is real, and in how far the theories are merely complements one of the other.

Dr. Simpson regards the advance of the stroke as dependent upon the flight of free electrons In this, the two theories agree. He says nothing about the source of the electrons, but I imagine that no serious objection will be raised to the assumption that essentially all result from collisions of rapidly moving electrons, or ions, with molecules. He pictures the positive stroke as the advance of a positively charged tongue extending from the cloud, the advance arising from a continuous sucking of electrons from an ionised region immediately ahead of the tip of the tongue, the branches of the stroke being formed in the same manner at places determined by the irregularities of the field.

But what ionises these regions ? If the field at the tip of the tongue is sufficiently intense, the positive ions in it will be driven forward with such velocity that they will ionise the air. In such fields, the electrons so liberated will be very effective ionisers, thus increasing the supply of electrons and of positive ions. Thus the tongue will advance as a result of the repulsion of its constituent ions, and the progress will be continuous so long as the field at the tip remains sufficiently intense If we regard the tip of the tongue as a region somewhat to the rear of the advance ions which produce the ionisation, this picture accords closely with what seems to be Dr Simpson's concept. Under favourable conditions, such an advance could certainly occur. But in order for branches to be formed by such a process, not only must the field be irregular, but also along the main spark the several regions of maximum lateral intensity must be small and quite definitely circumscribed.

It is difficult to believe that the field can have the very fine-grained structure necessary for the wonderfully rich development of branches which is frequently observed This seems to call for another explanation. Our present conceptions of the nature of the discharge of electricity through gases suggests that the branches are not outgrowths from the trunk, but ingrowths to it. In the region within which the intensity of the field is sufficient to confer upon a free electron the ionising velocity, there occurs, here and there, a stray free electron Each of these is sucked in by the field, and ionises the air along its path, and the electrons so freed join it in its flight. Thus each gives rise to an increasing swarm of electrons flying up the field. The number and distribution of the branches are determined, not by the irregularities of the field, but by the number and distribution of chance electrons. The trails of the electrons are positively charged; they are exactly similar to the tongue pictured by Dr. Simpson, but each arises from a negative stroke to the positive region, rather than as a positive stroke from that region. The trails extend the field, and may pick up other stray electrons which otherwise would not have been caught. Thus a branch may grow in length and may branch. In the same manner the main discharge, or tongue, may advance, not by pushing forward, but by successive negative strokes towards it. A much weaker field will suffice for this type of advance than for the other.

Even when there is ionisation by positive ions, there must in any actual case be ionisation by stray electrons also, and as the mobility of electrons far exceeds that of positive ions, it would seem that the path would be blazed by them rather than by the positive ions, and that the latter would merely enhance the charge of the blazed path and the current along it. In this case the path of the advance is determined by a succession of negative strokes, each starting from a stray electron at a distance from the tip of the tongue; and the effects of such a stroke will be similar to those produced by what I called an upward stroke of negative charge.

There seems to be no reason for doubting that a positively charged tongue, formed in either manner, might reach down into a region in which the field prior to its advent was very weak, or even adverse to the advance.

Dr. Simpson considers that the advance of a negatively charged tongue is impossible, because the mutual repulsion of the electrons would cause a continued broadening of the tip This, however, depends upon the conditions of the problem If the tongue consisted of a swarm of free electrons, and if it was not subjected to an external field, then it would certainly broaden out But if it is subjected to a longitudinal field which is intense as compared with the cross-field due to the mutual repulsion of its constituent electrons, then the paths of the electrons will make only small angles with the axis of the tongue, and at the tip the path will be axial. In this case, the growth will be axial, but there will be a lateral wastage. The electrons passing away from the axis will soon reach a field which is so weak that they lose their ionising power, become ions, and cease to migrate with significant velocity.

There are also other difficulties It is not clear how a negative tongue reaching some distance from a cloud can ever form if the field is not sufficiently intense to confer upon the positive residues an ionising velocity. If the positive residues take no active part in the ionisation, then as stray electrons near the cloud are driven away by the field, ionising the air as they go, they form a swarm of electrons which is separated from the cloud by a trail of positive residues. What is formed is not a tongue of negative ions reaching from the cloud, but a flying swarm, or dart, of electrons which is cut off from the cloud. On the other hand, if the field near the cloud is so intense that the positive residues acquire the ionising velocity, then they will serve as a continuing source of electrons, and a long tongue, or dart, of electrons will form Being subjected to the field of the dart as well as to that of the cloud, the forward portion of such a dart may acquire a tremendous velocity; this will facilitate its passage, and also reduce the lateral wastage But still there is no long tongue of negative ions extending from the cloud; there is nothing analogous to the tongue of positive ions, and apparently there cannot be. But there will be high-speed darts of free electrons. These and their highly ionised trails are essential features of the picture which

I proposed for the negative stroke. Many characteristics of lightning strokes can be satisfactorily correlated by means of such a concept.

With reference to the object struck, there are probably two main types of strokes: (1) The positive stroke, in which a positively charged tongue of ionised air extends from the cloud to the object; (2) the negative stroke by an electronic dart, of which the highly ionised trail extends from the cloud to the object. In general, the initial effects of the second will be more abrupt, more deep-seated, and more rending than those of the first.

The positive tongue theory advanced by Dr. Simpson and the electronic dart theory proposed by myself are not conflicting, but mutually complementary. The apparent conflicts, in so far as they are not a mere matter of words, arose solely from misconceptions, on one side or the other, regarding the completeness of the picture being presented.

N. ERNEST DORSEY.

2101 B Street, N.W.,
Washington, D.C.,
June 9.

IN the paper referred to by Dr. Dorsey, I discussed how a lightning flash is propagated from a positively charged cloud. In that paper, of set purpose, I did not discuss how the ionisation takes place, relying on the simple statement that ionisation does take place when and where the field exceeds a certain unspecified minimum value. I did this to avoid discussion of details which were unessential to the main purpose of the paper. But as Dr. Dorsey now raises these questions they must be considered, although the correspondence columns of NATURE are not appropriate for the full discussion which they really require. I must therefore be content with a few remarks on his main points.

There can be little doubt that free negative electrons which are always present in the atmosphere play some part in the ionisation accompanying a lightning discharge; but all the evidence, in particular the sharp boundary of the discharge channel, points to this action being confined to the immediate neighbourhood of the channel. In fact there is reason to believe that it is confined to the small region at the extreme tip of the advancing channel, where alone, in my opinion, the field is sufficiently strong to cause appreciable ionisation.

With regard to branching, Dr. Dorsey says: "Our present conceptions of the nature of the discharge of electricity through gases suggests that the branches are not outgrowths from the trunk, but ingrowths to it." I wonder to whom the word "our" in this sentence refers, for personally I cannot form any such conception. To me it is quite inconceivable that the branches grow from their tips inwards, finally uniting to form the trunk. This would mean that the electrical discharge starts in the weakest part of the field and not, as one would expect, where the field is strongest, near to the charged cloud.

The second half of Dr. Dorsey's letter is of more fundamental importance. He describes darts of negative electrons which are shot out of negatively charged clouds. It is not easy to understand Dr. Dorsey's ideas from this letter alone; but by reading his other publications I have come to the conclusion that his darts are very little different from the negative discharges which I considered and rejected in my Royal Society paper. I did not consider that such negative discharges are impossible "because the mutual repulsion of the electrons would cause a continued broadening of the tip," as stated by Dr. Dorsey. As a matter of fact, the mutual repulsion of the electrons never entered my head when writing the paper, for any such repulsion is infinitesimal in comparison with the fields which exist where ionisation takes place. The negative electrons would spread out at the tip of a negative discharge, if such could form, not because of mutual repulsion, but because the field under which the electrons move is divergent at the tip.

If it is granted that ionisation takes place where the field is a maximum, then the lines of force must diverge from that maximum. It is because the electrons move inwards for a positive discharge and outwards for a negative discharge that the former is possible and the latter impossible. It is this divergence of the field of force which would prevent the formation and existence of the darts imagined by Dr. Dorsey.

G. C. SIMPSON.

Butterfly Migration.

IN NATURE, September 5, 1925, Dr. E. P. Felt, State Entomologist of New York, in an article on the "Dispersal of Butterflies and Other Insects," said, "It is our belief that determinate flight is a comparatively small factor in promoting the spread of insects, and that in many cases this is accomplished largely by drifting with the wind, . . . There are a number of records of apparently determinate movement by butterflies, . . . These cases may represent a true migration, though this is scarcely established by available data."

In a later article, "Physical Basis of Insect Drift," NATURE, May 29, 1926, Dr. Felt continued the discussion and said, "the general tendency has been to explain any widespread movement as a migration, that is, a somewhat determinate or purposive movement by hosts of insects. This attitude is due in part to our very limited knowledge as to the movements of the upper air currents, . . . Turning to the western hemisphere, there are several records of enormous swarms of this butterfly, *Vanessa cardui*, being observed in apparent migration in southern California in 1924 and 1926, the movement being from the south-east to the north-west. One of the observers suggests that the source or the origin was either the foothills of the Sierras or the Sierras proper. There is a possibility that these swarms originated at a considerably greater distance. They may have been carried into the upper air in regions bordering desert areas considerably farther south or south-east, in much the same way as suggested for this insect in the eastern hemisphere, since we have in both extensive desert areas constantly producing convectional currents, and after a certain altitude is attained, the probabilities of extensive drift are certainly excellent."

Doubtless the movements of some insect swarms cannot be explained without the help of the winds. But what is needed, at least in the case of the California 'migrations,' before a general conclusion is drawn, is a careful accumulation of facts. In the early spring of 1926, there was a migration of the 'painted lady' through Palo Alto, California, in the Santa Clara Valley. The movement lasted several days and cannot by any possibility be explained by wind drift. Neither the origin nor outcome of this migration is known; it is not even known whether the swarm started from one area or was cumulative, picking up members as it went; but at the height of the movement the facts were so plain that they could not be misinterpreted. During the two days of March 25 and 26, 1926, I was out of doors nearly all the time and my official duties took me over an

potential of a substance has been established by Richardson, no further information on the nature of the a and b constants has been submitted so far.

I find on examination of the latest experimental data of S. Dushman, I. Langmuir, K. H. Kingdon, L. R. Koller, J. J. Weigle, C. Davisson and L. H. Germer, that, with absolute acceptance of those results for which greatest experimental accuracy may be claimed, and making slight allowance in those cases when, according to the investigators' records of experiments, and, in the case of S. Dushman, in accordance with the investigator's own opinion, such allowances appear to be warranted,

(1) 'a' can be expressed as an exponential function of molecular volume

$$a = Be^{-nv}$$

when B and n are constants.

(2) 'b' can be expressed as a hyperbolic function of molecular volume

$$b = Cv^{-m} - K$$

when C, m and K are constants.

There certainly may be doubt as to the validity of the 'a' equation, as, unfortunately, only six elements are available, and of these, three and two each give a common point on the semi-long curve.

No such doubt is attached to the validity of the 'b' equation, only one element, sodium, out of the fourteen elements, as divergent as tungsten and cæsium, appearing to be seriously out, and even in that case the discrepancy is capable of reduction in the light of Kingdon's equation.

Seasonal Sunshine in Great Britain.

IN reading the correspondence by Messrs Harding and Phillips, in NATURE of May 29, regarding the rival claims of the south-east and south-west of England as to sunshine, it seems desirable to point out that in over-stressing quite trivial differences there is some danger of losing sight of the really important climatic fact of sensible equality between the two districts. The difference, for example, quoted between the average daily amount of sunshine through the year, namely, 4·53-4·49 hours, is just about two minutes a day in favour of the south-western counties. Even if such a difference deduced from a limited number of stations over no more than 35 years is real, which may be doubted, it could scarcely be of any medical or other practical importance.

Mr Phillips objects to the inclusion of South Wales with the south-west counties on the ground that it lowers the sunshine values for the south-west district. The fact, however, that it does so rather tells, in my opinion, in favour of the south-east district, because the sunny conditions of the entire south coast of England stretch much farther north up the east coast than they do up the west coast, leaving the south-east district more centrally situated in the bright belt than the south west. This may be verified from the sunshine maps in "Book of Normals," Sect. III, and may have some significance.

Sunshine is one of several elements that indicate a sharper seasonal variation when the daylight quarters are employed in preference to the thermal quarters which lag a month behind, namely, November-January, rather than December-February, etc. Still better is the seasonal variation exhibited by taking the four-month summer and winter (May-August) and (Nov.-Feb.) respectively, with the two pairs of equinoctial months for spring and autumn—a scheme coming increasingly into vogue. The English climate is such that the average meteorological sunniness or percentage of possible amount varies in the same sense as the astronomical sunniness or length of day. The result is that the actual amount of sunshine exhibits a very close relationship to the solstices in a land where the days are only $7\frac{1}{2}$ hours at the low solstice and as much as $16\frac{1}{2}$ hours at the high solstice. There are some climates, on the contrary, where, with cloudy summers and clear winters, the summer excess of sunshine is but slight.

Spatial Relations in a Dream.

IN a letter in NATURE of March 17, 1923, Mr. Gheury de Bray described some observations on time relations in a dream. He mentioned that hypnopompic (or hypnostrophic) images "are generally landscapes passing slowly before one's closed eyes, when in an almost awake condition . . . and having one's full reasoning powers while the illusion proceeds." It seemed "that the speed of succession of the images is an inverse function of the degree of wakefulness." A recent experience would tend to confirm these observations. A succession of faintly coloured landscape images was followed by a less ephemeral and apparently more vivid landscape, while there intruded, at first faintly, then more distinctly, sounds which became identified as knocking on the door. In the dream, the image (a well-known landscape) appeared as if the observer were in a vertical position. But after (? during) the disturbing sounds, an awareness of the actual (*i.e.* horizontal) position of the observer resulted in a conformable orientation of the image. As the observer was lying on his right side, the image seemed to have rotated 90° to the right, and thus the same relative position of observer and image, and also the continuity of the dream, were apparently preserved until completion of the wakening process.

Television or Teleoptics?

IS it too late to enter emphatic protest against admitting into English vocabulary such an excruciating hybrid as 'television'? I am afraid it is, otherwise this term would not have appeared in this journal (July 3, p. 18) as the title of A. R.'s interesting paper, thereby receiving the *cachet* of NATURE. Hitherto the terminology of science has been framed in scrupulous conformity with the unwritten law or rule against the fusion of different languages in a compound vocable. In this case there is all the less occasion for relaxing the rule because there is ready to hand the term τὰ ὀπτικά, employed by Aristotle to denote all that relates to vision—optics. Surely 'teleoptics' would be as convenient a name as the cacophonous 'television,' and would not upset the equanimity of pedants like myself.

HERBERT MAXWELL.

Monreith.

Rotation and Relativity.

THE case of a vortex ring appears to have a special bearing on the question of rotation in relation to the relativity theory. An observer regarding such a ring can establish definitely that the ring is rotating with respect to himself, but not he with respect to the ring, as in the latter case he would see the ring pass round him, himself passing through the ring (together with the rest of the universe) at each revolution. These two cases are not equivalent, and it is suggested that this affords proof that rotation is not relative, but absolute.

Meteors and the Constitution of the Upper Air.

By Prof. F. A. LINDEMANN, F.R.S.

FROM the earliest times meteors and meteorites have probably been objects of wonder and interest. Astronomers have examined their radiants and established their connexion with certain comets, and physicists have been led by the study of their characteristics to quite unexpected conclusions about the conditions of the atmosphere at great heights. It is these latter developments that it is proposed to describe as briefly as possible.

Practically all meteorites which have been analysed are mixtures of metallic iron-nickel and of an olivine-like glass consisting of a double silicate of magnesium and aluminium, the proportions ranging from pure metal to pure glass. Since there is no real line to be drawn between meteorites and meteors, it seems legitimate to infer that meteors are composed of the same materials. Meteors appear at heights between 150 and 80 kilometres, and disappear at any height above ground-level, the meteorites of course actually reaching the ground. Their brightness varies within wide limits from the faint telescopic meteors invisible to the naked eye to the fire-balls said to rival the sun in brilliance, and their visible life may be anything between a fraction of a second and some fifteen seconds. Their recorded velocities range from some 10 km./sec. to about 100 km./sec., but it is clear from the nature of the case that these figures, especially in the higher ranges, cannot pretend to any great accuracy any more than can the estimates of luminosity. Deceleration along the path has never been certainly observed.

Presumably everybody would agree that meteors are extra-terrestrial particles moving with planetary velocities brought to incandescence by friction against the air. If further information, however, is desired, it is necessary to formulate somewhat more precisely what occurs when the meteor enters the atmosphere. To fix one's ideas it is as well to have in mind a typical meteor, for example, a meteor which appears at a height of 100 kilometres and disappears at a height of 80 kilometres after traversing a path of 60 kilometres in 1·5 seconds. It may be assumed that this meteor appears as bright at a distance of 150 kilometres as a first magnitude star, *i.e.* that it radiates in the 1·5 seconds of its visible life $3{\cdot}3 \times 10^{10}$ ergs.

The first question to be examined is the original size of the meteor. It is easy to show that practically all its initial energy will be converted into radiation; for its speed relative to the air is so great, and collisions between particles moving at this speed and air molecules consequently so violent, that they disturb the electrons: sooner or later these must return to their normal orbits, entailing, of course, the emission of radiation. If all the energy appears as radiation it is simple to calculate the mass of the particle. The total energy is $3{\cdot}3 \times 10^{10}$ ergs, the velocities 40 km./sec., so that its initial mass must have been 0·25 milligrams. If composed of iron, therefore, such a typical meteor would consist of a particle of diameter 1·15 millimetres, *i.e.* about as large as a small shot.

It is now possible to examine what occurs when such a particle approaches the earth's atmosphere. At first the atmospheric molecules are so rare that the effect of one collision with a molecule will have been dissipated before the next occurs. The result of such collisions will be inappreciable. Most of the energy will be used up in ionising and breaking up the molecules, a part will be radiated, a smaller part will perhaps cause local heating and evaporation, but enough light to render the meteor visible cannot be produced. As the meteor approaches the earth, the density of the air increases and the frequency of these impacts becomes greater, until at a certain height the original colliding molecules and the evaporated meteoric molecules have not time to escape laterally from in front of the advancing meteor before they again collide with air molecules. It is in this region that a cap of gas begins to form in front of the particle which protects it from direct impacts and from loss of heat. Heat now begins to flow from this compressed and heated cap of gas into the particle, ultimately causing it to volatilise.

It is only when evaporation is appreciable that a meteor becomes visible. However hot it might be, a particle the size of which is measured in millimetres could not be seen at a distance of a hundred kilometres; when it evaporates its vapour spreads out and is brought to rest by collision with the molecules of the air in a comparatively large cross-section. The radiation emitted in this process from an effective surface measured in square centimetres is what is observed.

It may readily be seen how this qualitative description may be put upon a quantitative basis, and used to obtain information about conditions in the upper air. Meteors cannot appear until the cap of gas begins to form, *i.e.* until the chance of a molecule escaping laterally without further collision with an air molecule is small. We know the speed at which the meteor is travelling; we can make a fairly close estimate of the average lateral component of velocity of the escaping molecules; and, as shown above, we can calculate the size of any particular meteor the distance, brightness, duration and speed of which are known. Therefore we can calculate what the density of the air must have been if a cap was to be formed. This should represent a minimum value for the density at the height of appearance of the meteor. Fig. 1 shows the calculated densities plotted on a logarithmic scale against the height of appearance of sixty-five meteors the speed, brightness, etc., of which had been observed.

A second check may be attained by considering what happens after the cap has formed. A simple application of the kinetic theory of gases enables one to calculate what fraction of the total heat produced by the impact of the moving meteor upon the air will actually flow through the cap into the meteor and become available for heating and finally volatilising it. The total heat is of course equal to the amount of air accelerated in unit time, *i.e.* the product of the atmospheric density with the cross-section and velocity of the meteor, multiplied by one-half the square of its velocity. Hence the flow of energy available for heating or volatilising in terms of the atmospheric density can be determined. Since we are fairly certain of the size and constitution and consequently heat capacity and latent heat of each meteor, we can calculate the

amount of heat necessary to raise it to a temperature at which evaporation takes place (the point at which the meteor should appear), and also the amount of heat necessary to complete the meteor's evaporation (the point at which the meteor should disappear). Therefore the heights of appearance and disappearance can

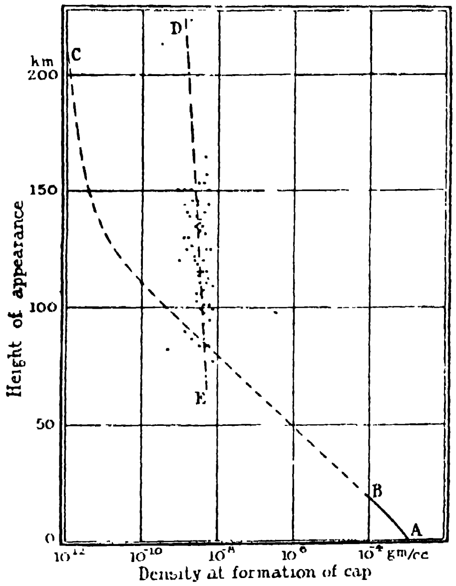

FIG. 1.

be calculated in terms of the observed meteoric characteristics and the atmospheric density, or inversely the atmospheric density can be calculated from the meteoric characteristics. Fig. 2 shows densities calculated on this basis for some hundred meteors plotted as crosses and dots against their heights of appearance and disappearance.

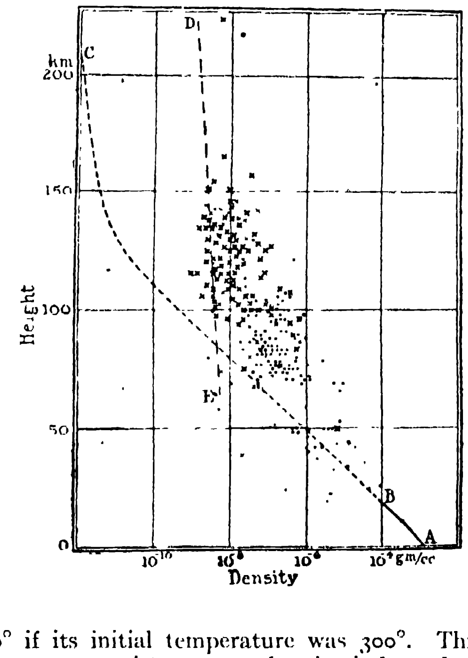
Though one could wish these points lay more closely upon a curve, their agreement may be regarded as satisfactory considering the uncertainty in the observational data, introduced more especially by the determination of the meteor's velocities. The two methods agree quite well among themselves, as is shown by the line DE repeated in Fig. 2 from Fig. 1.

In both figures the line AB represents the density of the air derived from *ballon sondes* observation and the dotted line BC the density calculated, assuming the observed temperature of 220° Abs. at a height of 11 kilometres to remain constant up to the confines of the atmosphere. It is clear that at great heights both methods give very much higher densities than correspond to this assumption. The only reasonable interpretation of the discrepancy seems to be that one is not justified in assuming that the temperature is constant from 25 km. to 150 km. simply because it has been shown to be constant between 11 km. and 25 km. In the accompanying figures the immediate observation of the temperature extends from A to B. In view of the evidence obtained from meteors, it seems quite unjustifiable to extrapolate from B to C. The meteor results would be satisfied if one assumed that the atmospheric temperature increased at heights above about 50 kilometres to something of the same order as the earth's surface temperature or perhaps somewhat higher.

This assumption may be supported by two lines of argument: the first is that further experimental facts seem to accord with it; the second is that it is to be expected *a priori* on the ground of known physical laws.

We may first consider four empirical facts which seem to agree with the view that the temperature at great heights is considerably higher than 220° Abs., the first two based on observations of meteors, the last two upon quite independent phenomena.

As has been pointed out, meteorites consist almost without exception of two components, nickel-iron and a glassy olivine-like substance mixed in varying proportions. It has been shown that a meteor can only become visible if it evaporates; therefore the temperature in the cap of compressed gas in front of the meteor must attain a temperature at which iron or olivine evaporate if the meteor is to appear. Now the maximum temperature which gas can attain under adiabatic compression is readily calculated if one knows the initial temperature and the compression ratio. In the case we are considering it may be shown that the compression ratio is $3v^2/2V_0^2$, v being the meteor's velocity and V_0 the molecular velocity. Hence the maximum temperature at the meteor's surface can be determined in terms of the velocity of the meteor and of the initial temperature of the air. Iron and olivine will only evaporate sufficiently rapidly to give rise to a visible meteor if the temperature is above 2000°. Meteors have been observed moving at a velocity of 12 km. per sec. Our formula tells us that air compressed by a particle moving at 12 km. per sec. can only reach



2000° if its initial temperature was 300°. This provides a very satisfactory and quite independent confirmation of the previous result.

A second somewhat more doubtful check may be found if the number of meteors which disappear at various heights is examined. It is found that whilst many meteors disappear between 100 km. and 60 km.

and many below 50 km., scarcely any disappear between 50 km. and 60 km. So far only one reason has been put forward to account for this quite unexpected fact. As we have seen, the hotter the air is, the greater the flow of heat into the meteor. For a meteor approaching the earth there should be, on our theory, a region in which the air's initial temperature falls from 300° to 220°, giving rise to a corresponding fall in the flow of heat. In this region one would expect a slower rate of evaporation and therefore diminished luminosity; this effect would, however, soon be outweighed by the increased friction and heat production due to increased air density. It is clear that such a region is the most unlikely one for a meteor to disappear; if it reaches it at all it will probably penetrate into the cooler but denser atmosphere below. The only explanation for the fact that no meteors have been observed to disappear at 55 km. seems to be that somewhere between say 52 km. and 57 km. the temperature of the air rises from the 220° of the stratosphere to the higher temperatures in the neighbourhood of 300° of the outer regions.

This view is confirmed in two very striking ways. As is well known, sources of sound are surrounded by alternate zones of audibility and silence. The distribution of these zones has been explained by the assumption that the velocity of sound increases at great heights. Recent investigations have shown that the height at which this increase should occur in order to account for the observed facts is of the order of 50 km. Clearly the well-known increase in velocity of sound with temperature would explain this otherwise inexplicable acoustical phenomenon if the view put forward above is correct, namely, that the temperature increases rapidly with height in this region.

A fourth argument in favour of this, though as yet not really a convincing one, is found in the well-known anomalies in the propagation of wireless waves. Notoriously the observed facts seem explicable only on the assumption that there is a conducting layer, the Heaviside layer, at a height varying from 50 km. at sunset to some 80 km. at sunrise. One can, with some plausibility, attribute this conducting layer to solar ionisation by day, but it seems difficult to account for its persistence at night otherwise than by assuming that the solar radiation forms some unstable compound which gradually reacts or breaks up forming ions during the hours of darkness. Such a substance is ozone, and it is clear, owing to the enormous increase in the rate of reaction with temperature, that the layer of maximum ionisation after sunset will be the lowest layer at which a high temperature exists, and that this will move up as the ozone is used up during the night to regions of lower density in which the rate of reaction is smaller. This hypothesis, of course, awaits many further checks, *e.g.* by observations at high latitudes during the polar night; but whatever the outcome, the observed fact that the height of the Heaviside layer after sunset lies between 50 km. and 60 km. seems very significant.

Finally, it might be worth while to discuss briefly the theoretical aspect of the high temperatures which observation seems to imply. Roughly speaking, above the troposphere, the region of convective equilibrium, the temperature is determined by radiation alone. Clearly a black or grey body would reach the mean temperature of the earth's surface, for this is the temperature at which emission balances absorption. The gases of the atmosphere are scarcely to be compared to black or grey bodies, however. The main constituents are, from the radiative point of view, somewhat dull and inert. Apart from the rather weak bands of oxygen in the red, neither oxygen, nitrogen nor argon has any well-marked absorption, and therefore emission bands at wave-lengths greater than 2000 Å.U., *i.e.* those to which practically all the sun's emission is confined. Infra-red absorption seems to be the function of the water-vapour, carbonic acid and the ozone. Now if one has a gas with strong absorption bands, even if mixed only in a small proportion with a neutral gas such as nitrogen, it will impose upon the whole mixture its own radiative equilibrium temperature. For the active gas will absorb radiation, and either pass it on to the neutral gas by a 'collision of the second sort' (Stoss zweiter Art) or re-emit it. Equilibrium between energy loss by impacts and gain from collisions will be established when the temperatures are equal. Hence we need only consider the 'active' gases water-vapour, carbon dioxide, ozone and oxygen.

Immediately above the troposphere, say from 10 km. to 50 km., the effect of the oxygen will be unimportant. Its absorption in the visible region is small; the rays it can absorb in the far ultra-violet will have been filtered out by the oxygen above. The influence of ozone might be more important, but it will be far outweighed by the effect of the water-vapour and the carbonic acid, the concentration of which in this region is considerable. The concentration of water-vapour at 11 km. will probably be about $2{\cdot}5 \times 10^{-8}$ gm./cm.^{3}, falling to about 4×10^{-10} gm./cm.^{3} at 55 km. The concentration of carbonic acid will be about $1{\cdot}2 \times 10^{-7}$ gm./cm.^{3} at 11 km., falling to about $7{\cdot}5 \times 10^{-12}$ gm./cm. at 55 km. The total amount of ozone above 11 km. amounts to about $1{\cdot}4 \times 10^{-5}$ of the whole amount of oxygen above this level, but its exact distribution is at present unknown. Presumably it is formed by the sun's ultra-violet radiation, which is absorbed by oxygen at wave-lengths below 2000 Å.U. In this case the amount formed per cm.^{3} must reach a maximum somewhere in the neighbourhood of 60 km. At greater heights the decrease in the partial pressure of oxygen outweighs the increase in intensity of the solar radiation. At lesser heights so much of the initial radiation of the effective wave-length has been absorbed that its loss is not counter-balanced by the increased concentration of oxygen. Hence it is above 50 km. that the concentration of ozone compared to the concentration of water-vapour and carbonic acid becomes important.

Now the equilibrium temperature of the air will be some sort of mean between the equilibrium temperatures in these three gases. The equilibrium temperature of carbon dioxide is easy to calculate. It has only one strong absorption band at $14{\cdot}6\mu$, and its temperature will be found by equating the emission from this band to the absorption. Since there is very little energy in this part of the solar spectrum, the carbon dioxide only absorbs energy from the layers below, more especially the earth, whilst it radiates both upwards and downwards. Its equilibrium temperature is therefore low, about 236°. The value for water-vapour is not so easy to determine, on account of its complicated absorption spectrum. It also absorbs in the infra-red only, and

therefore has a low equilibrium temperature, probably between 200° and 220°. The case of ozone is even more complicated, since it absorbs not only at $9{\cdot}5\mu$ but also to a certain extent in the visible and very strongly in the ultra-violet below 3000 Å.U. Since a not inconsiderable fraction of the sun's radiation (probably more than 1 per cent.) lies in this region, this amount of heat as well as that abstracted from the visible part of the spectrum has to be accounted for in some form or other. It can only be re-emitted by pure ozone at a wave-length of $9{\cdot}5\mu$, and its equilibrium temperature when exposed to sunlight and the earth's radiation would therefore be correspondingly high, probably well above 300°.

The general picture may therefore be drawn in outline as follows. At low heights in the troposphere we have convection and therefore an adiabatic temperature gradient. Above 11 km., at which height the temperature has fallen to the equilibrium radiative temperature, *i.e.* 220°, convection will be damped out. From here on one should have a compromise between the radiative equilibrium temperatures of the various active gases. At 11 km. the effect of water and carbon dioxide will preponderate and a low temperature will obtain, but as one ascends, the carbon dioxide disappears and the water diminishes, whilst the ozone with its high equilibrium temperature will become more and more dominant. Above 60 km. the effect of ozone should outweigh that of the other gases and the air should approach the equilibrium temperature of this gas, *i.e.* about 300°, as is indicated by the various more empirical arguments we have outlined.

Whether the agreement of all these forms of indirect reasoning is regarded as convincing is of course a matter of personal opinion. Final certainty can only be attained by direct measurement. It is much to be desired that such immediate observations be made at the earliest possible moment, but the expense and difficulty at present seem to be prohibitive.

Methods and Results of the American Museum Expeditions in the Gobi Desert, 1922-25.[1]

By Prof. HENRY FAIRFIELD OSBORN, For. Mem. R.S.

A NEW volume in the life-history of the earth, composed up to the present of twenty-four chapters (see table below), has been revealed by the discoveries of the Mongolian Expeditions of the American Museum of Natural History, under the leadership of Roy Chapman Andrews. Central Asia, and especially the region east and south-east of Chinese Turkestan, long remained the *terra incognita* of geology, palæontology, and, in a minor sense, of geography. In 1900 the lecturer predicted that the unknown high-plateau region of Central Asia, rather than the well-known Asiatic provinces on the south, such as the Siwalik Hills of India, explored by Hugh Falconer (1830–50), would prove to be the chief centre of the origin and distribution of the mammalia from which waves of north mammalian life radiated to the continents of Europe and of North America.

Andrews's expeditions in the three seasons of 1922, 1923, and 1925, have not only completely verified this prediction, but have also revealed the high Central Asiatic plateau region as the chief home of the terrestrial deinosaurian reptiles of Upper Jurassic and of Cretaceous time. In brief, these discoveries establish Mongolia as a chief centre of northern terrestrial life-history, from the close of Jurassic time onwards to the very close of Pleistocene time.

From the point of view of palæogeography, the outstanding geological discoveries of the expedition are:

First, this Central Asiatic continent of Gobia, as it has been named by Grabau, was for several millions of years extremely favourable to the evolution of reptiles, mammals, insects, and plants, and probably birds as well, hitherto known along the low-lying Cretaceous forelands of western Europe (such as the Wealden of England and Belgium), and in less degree of southern Asia. Secondly, this now terribly desert region of Gobia, traversed only by the gazelle and the wild ass, and thoroughly uninhabitable in the summer season, was abounding in life throughout Upper Jurassic, and throughout all Cretaceous and Tertiary time, sparsely forested, traversed by streams and rivers, with a limited seasonal rain-supply like the high-plateau region of Central Africa to-day. Thirdly, these dry and stimulating upland conditions of Tertiary time, as compared with the densely forested conditions of the Asiatic lowlands, have led to the recent prediction by the lecturer on returning from Iren Dabasu in 1923, that this region is the most likely one in which to search for the Tertiary ancestors of man, namely, those of Eolithic or Dawn-stone Age, though no traces of man have, as yet, been discovered by the expedition older than those of Lower Palæolithic age. The discovery of human and pre human remains in Tertiary time has thus become one of the chief remaining objects of the expedition.

During the season of 1925 a great culture-camp, probably of Azilian-Campignian time, was discovered on the eastern slopes of the Altai Range, not far from Shabarakh, and not far from Djadokhta, where the now famous deinosaur eggs were discovered, far north of the Ordos locality explored by Licent and Teilhard de Chardin. In fact, these Upper Palæolithic artisans collected the broken shells of the deinosaur eggs with which to manufacture necklace ornaments, these perforated fossil shells serving as well as the recent eggshells of the giant Struthiolithus, the great ostrich of the Stone Age of Mongolia.

No human fossils have so far been found: the industrial levels are not as yet precisely determinable, but the chief anthropological fact is established that the Stone Age tribes spread over the borders of the Gobi Desert region during the Ice Age, establishing their quarries near the large lakes bordering the Altai Mountains on the east and fed by glacial streams. The geologists of the party have discovered traces of this glacial age along the summits of the Altai Range.

As for methods, by combining a very large caravan for the camel transport, which leaves Kalgan on December 1, and reaches the eastern base of the Altai Range on May 1, with an automobile train of five to

[1] Abstract of a lecture delivered by the author to the Geological Society of London on June 23.

seven cars, the expedition had the great advantage of speed over the previous geological explorers who crossed the Desert with camels only. The geologists and palæontologists of the party, Granger, Berkey, and Morris, with two field assistants, also had the advantage of prolonged experience in the field formations of the western United States, which, between the 50th and 40th parallels of latitude, present conditions remarkably similar to those found in the Desert of Gobi. Raphael Pumpelly in 1864, Ferdinand von Richthofen in 1872, and V. A. Obruchev in 1909, found no fossils, except the single rhinoceros-tooth brought back by Obruchev; and other geologists traversing this region have thought that there were no fossils to be found.

As to geology, the expeditions beginning on April 15, 1922, 260 miles north-west of Kalgan, and encircling in 1922, 1923, and 1925, the entire Gobi district in a 3000-mile radius, discovered no fewer than twenty-three distinct geological formations extending downwards from Lower Pleistocene time into Lower Cretaceous and Upper Jurassic. These have a thickness varying from 50 to 3000 feet, and were deposited either in the great flood-plains of ancient rivers, or in broad river-valleys, or at the base of ancient mountain-chains, or in the torrents of great sand-storms such as the Djadokhta, testifying to the secular vicissitudes of climate, mostly of rainfall, terminating with the pluvial period of the Ice Age, followed by a long period of secular desiccation.

Some of these formations prove to be closely contemporaneous with the Lower Cretaceous Wealden of western Europe, owing to the presence of large iguanodonts, equalling the famous *I. bernissartiensis* of Belgium in size. The oldest are as early as the Oxfordian and Purbeck of Upper Jurassic times. The climax of reptilian life is reached in the marvellous sand-swept deinosaur breeding-grounds (Djadokta formation) of Middle Cretaceous time, where nests of fossil eggs and innumerable skulls and skeletons of Protoceratops are found in almost perfect preservation. This is the richest deinosaur deposit thus far discovered in Eurasia.

As to the fifteen succeeding Tertiary formations, they compose so many unbroken chapters of the history of Mongolian life as extend from the basal Eocene Gashato to Upper Oligocene time, where the giant Baluchitherium occurs, as discovered also in Baluchistan by Cooper of Cambridge, and in Chinese Turkestan by Borissiak of Moscow. The Miocene and the Pliocene periods are represented by four formations.

Thus the scientific staff of the Expedition, between the years 1922 and 1925, has interpreted one of the most typically desert regions of the entire world by means of the twin sciences of palæontology and geology, and the wilderness of Mongolia now blossoms forth with its glorious story of prehistoric life, as the homeland of the greater number of known upland terrestrial vertebrates.

STONE AGE, TERTIARY, AND CRETACEOUS FORMATIONS OF MONGOLIA, IN DESCENDING ORDER

Regions	*Formations and Thickness estimated in feet*		*Probable or estimated Geological Age*	*Human Culture, Mammalian and Reptilian Life-zones.*
Altai Piedmont	Shabarakh Usu	50 +	Upper Palæolithic	? Azilian Campignian
,, ,,	Orok Nor	5–40	Middle Palæolithic	? Aurignacian Mousterian
			Lower Palæolithic	? Acheulean or ? Eolithic.
Orok Nor basin	Khunuk	27–120	Lower Pleistocene	? Equus, ? Mastodon
Tsagan Nor basin	{ Tsagan Nuru / Gochu }	{ 50 + / 1000 + }	Lower Pleistocene	? Equus, ? Struthiolithus.
Eastern Altai Mt	Hung Kureh	1000	Upper Pliocene to Lower Pleistocene	Hipparion Camelus zone
Iren Dabasu basin	Pang Kiang	500	Miocene, age doubtful	Rodents ? Ochotona.
Eastern Altai Mts	Loh	100–1000	Middle Miocene	Mastodon (Serridentinus) zone.
,, ,, ,,	Hsanda Gol	3000	Middle to Upper Oligocene	*Baluchitherium grangeri* zone
Iren Dabasu basin	Houldjin	30–50	,, ,, ,,	,, ,, ,,
Orok Nor basin	Elegen	0–200	,, ,, ,,	? Mammals undetermined
Chassutai Trail	Baron Sog	5–30	Middle Oligocene	? Large Titanotheres
,, ,,	Ulan Gochu	?–60	Lower Oligocene	? ,, ,,
Chassutai Trail	Ardyn Obo	500	,,	*Brontops gobiensis* zone
,, ,,	Shara Murun	200	Summit of Eocene	*Protitanotherium mongoliense* zone. *Amynodon mongoliensis*.
Shara Murun basin	Tukhum	50 +	Upper Eocene	Titanotheres abundant.
Iren Dabasu basin	Irdin Manha	? 100	,, ,,	Eudinoceras, Andrewsarchus zone.
,, ,, ,,	Arshanto	40–100	? Middle Eocene	Lophiodonts Schlosseria zone
Kholobolchi Nor basin	Kholobolchi	1000	? Lower Eocene	Coryphodon zone
Eastern Altai Mts	Gashato	300	Basal Eocene (Palæocene)	Prodinoceras zone Palæostylops.
Eastern Altai Mts	Djadokhta	500	Middle Cretaceous	Protoceratops andrewsi zone
N.-E. of Shabarakh Usu	Dohoin Usu	200 +		Deinosauria, Crocodilia Chelonia zone
Iren Dabasu basin	Iren Dabasu	180	Lower Cretaceous ? Wealden	Iguanodont Ornithomimidæ
Oshih basin	Ashile	2000	Upper Jurassic	Psittacosaurus zone Asiatosaurus. Prodeinodon
Tsagan Nor basin	Ondai Sair	500	,, ,,	Protiguanodon zone.

The British Association at Oxford.

BY the time that the present issue of NATURE is in the readers' hands, the meeting of the British Association for the Advancement of Science will be in full progress. The Sheldonian Theatre, where Mr. Disraeli made the celebrated announcement that he was "on the side of the angels," will have been the scene of yet another important gathering; and the chief social events of the meeting, namely, the receptions by the Vice-Chancellor, the Mayor, and the Dean, Canons, and students of Christ Church, will have taken place at the Examination Schools, the Town Hall, and Wolsey's great foundation respectively.

Among the institutions of Oxford which combine historical with scientific interest, not least must be reckoned the Botanic Garden on the south side of the High Street, opposite Magdalen College. This, the earliest botanic garden now existing in England, was founded by Henry, Lord Danvers, in 1621, and was intended by him to be put in the charge of John Tradescant, gardener to King Charles I., who, however, died before the appointment took effect. The scientific movement in Oxford, which began in the days of the Commonwealth under the auspices of John Wilkins and his associates, and culminated in the establishment of the Royal Society soon after the Restoration, was carried on by Elias Ashmole. It was to Ashmole that the younger Tradescant bequeathed the natural history and antiquarian collection begun by his father, and to Ashmole himself the University was indebted for the gift of the Tradescant collections, to which that industrious collector had made large and important additions.

It was not until 1669 that Lord Danby's 'physick garden,' which had failed to secure the services of either Tradescant, was equipped with a regular professor. This was Dr. Robert Morison, who delivered courses of lectures, one of which was attended in 1675 by John Evelyn. A great benefactor to the establishment was Dr. William Sherard, who left a permanent endowment for the professorship of botany. It was Sherard who invited the famous Dillenius to take up his residence in England, and provided, by the terms of his will, that Dillenius should be the first occupant of the Sherardian chair. Linnæus, who visited Oxford in 1736, was entertained by the professor, and endeavoured, though without success, to convert him to his new system of classification. In spite of their inability to see eye to eye in botanical matters, the two men formed the highest opinion of each other's merits. The Oxford professor, for his part, "detained Linnæus for a month without giving him an hour to himself the whole day long; and at last took leave of him with tears in his eyes, after having given him the choice of living with him till his death, as the salary of the professorship was sufficient for them both." The Swedish botanist declined this generous offer, but after his return home wrote, "In Anglia nullus est qui genera curet vel intelligat praeterquam Dillenius," and moreover, "founded the genus Dillenia, of all plants the most distinguished for the beauty of its flower and fruit, like Dillenius among botanists" (Gunther, quoting Claridge Druce).

The next professor, Dr. Humphrey Sibthorpe, is said to have given only one lecture, and that a bad one; but his son and successor John was a man of different stamp. Besides projecting and partly carrying out a great work on the flora of Greece, he founded and endowed the professorship of rural economy which still exists.

A new epoch of efficiency and activity dawned with the appointment of Dr. Daubeny in 1834. The energy and persistence of the new professor speedily resulted in considerable additions to the buildings and in extensive improvements in the usefulness and attractiveness of the garden. The reforms set on foot by Daubeny have been continued and developed by his successors, notably by Bayley Balfour, Sidney Vines, and the present occupant of the chair of botany, Sir Frederick Keeble.

Part of the extensive scheme devised by Acland for bringing together in one place all the various departments of natural science, with the view of "the development of a complete national education in science," involved the removal of the lecture-rooms, laboratories, and other appliances for botanical study to the neighbourhood of the new museum, while a 'garden of instruction,' some five acres in extent, would have been established in the Parks. A clever skit by Mr. Edward Chapman, of Magdalen College, cast ridicule on the scheme and did much to cause its abandonment. Many, however, will still think that the plan had great advantages; and it is to be observed that it has since been found quite impossible to carry out within the precincts of the ancient garden all the botanical teaching which has now become necessary.

A very attractive feature of the present meeting will be the opportunity of visiting, by the kindness respectively of Mrs. G. H. Morrell, Sir Arthur Evans, and Mr. Henry Balfour, their exceptionally fine gardens and grounds in the immediate neighbourhood of Oxford. The grounds of Headington Hill Hall, the residence of Mrs. Morrell, are far-famed for their beauty, their extent, and their picturesque situation on the side of the hill overlooking the city. From them can be seen the best views of the University and College buildings to be had anywhere. Youlbury (Sir Arthur Evans) and Langley Lodge (Mr. H. Balfour) have also their own points of exceptional beauty and interest. As an example of a city garden, that of Exeter College, with its boundary formed by the Divinity School and the library of Humphrey Duke of Gloucester, cannot easily be surpassed. The party to be given in these pleasant surroundings by the Rector and Fellows of the College is certain to be highly appreciated by their guests.

The conversaziones to be held at the Ashmolean and University Museums on the evening of August 10 will end the public entertainments of the present meeting. Both are likely to be especially attractive to the devotees of the arts and sciences respectively. The short lectures, demonstrations, and exhibits at the University Museum have been chiefly organised by members of the Junior Scientific Society of the University, an association the zeal and activity of which are among the most hopeful signs of present-day life in Oxford. F. A. D.

Dr. D. H. Scott writes: "In addition to the list given in NATURE of July 31 of distinguished guests from abroad attending the Oxford meeting of the British Association, may I mention that we are also expecting Dr. R. Kräusel, of Frankfurt? In conjunction with Dr. H. Weyland, Dr. Kräusel has made important discoveries in the Middle Devonian flora, showing that the plants of that early period were considerably more advanced than had been realised before. He is giving an account of his results in the Section of Botany."

Obituary.

REV. T. R. R. STEBBING, F.R.S.

THERE must be very many students of the Crustacea scattered all over the world who will read with a sense of personal loss that the Rev. T. R. R. Stebbing is dead. Some of us who are now grey-haired look back to the time when we first discovered the unfailing kindness and patience which allowed the most ignorant beginner to dip into his endless stores of knowledge, and find it hard to realise that we can no longer 'ask Stebbing' when we come to some particularly knotty point in nomenclature or bibliography.

Thomas Roscoe Rede Stebbing was the son of the Rev. Henry Stebbing, D.D. He was born in London on February 6, 1835, and was the seventh in a family of thirteen, several of whom inherited the literary tastes and abilities of their father. From King's College School he went to Lincoln College and later to Worcester College, Oxford. His academic career was distinguished, but his studies were exclusively classical and literary. He obtained a second in *Lit. Hum.* in 1856 and a first in law and modern history in 1857. In 1858 he took orders, being ordained, it is interesting now to recall, by the Bishop of Oxford, Samuel Wilberforce. Masterships at Radley and Wellington were followed by a fellowship and tutorship at Worcester College, of which he was in turn vice-provost and dean.

Stebbing resigned his fellowship in 1867 on his marriage with Mary Anne, daughter of W. W. Saunders, F.R.S., the well-known entomologist, and took pupils, first at Reigate and afterwards at Torquay. At Torquay he became acquainted with some enthusiastic local naturalists, among whom was William Pengelly, under whose inspiration he began to take an interest in natural history. He has told how it was that, already in middle age, he was led to the serious study of zoology. "Having become much interested in Natural Science, and having also been trained in the strictest school of evangelical theology, I had conceived it to be a duty to confute the vagaries of Darwin. But, on reading the 'Origin of Species,' as a preliminary, it has to be confessed that, instead of confuting, I became his ardent disciple." He threw himself into the controversy then raging, and a volume of "Essays on Darwinism" published in 1871, as well as a letter to NATURE in April of the same year, replying to a scornful *Times* review of the "Descent of Man," drew upon him, as we may gather, a good deal of ecclesiastical hostility. From then onwards he continued his advocacy of a liberal theology in essays and magazine articles, some of which are reprinted in his "Faith in Fetters" (1919) and "Plain Speaking" published only a few months ago. Some of these essays now read like echoes of "old, unhappy, far-off things,"—so far off, at any rate, as Dayton, Tennessee!

It was a desire to become acquainted at first hand with some of the facts of Nature on which the evolution theory rested that led Stebbing to take up the study of Crustacea. After some early papers on British species he was entrusted, on the recommendation of his friend Canon A. M. Norman, with the description of the Amphipoda obtained by the *Challenger* expedition. He gave up teaching in order to devote himself to this task, and after some six years' work he produced his report (1888), which fills three of the large quarto volumes of the *Challenger* series. It is not too much to say that this report set a new standard for systematic carcinology, especially in its admirable bibliographical introduction, giving a critical analysis of everything that had been written on the Amphipoda down to the year of its publication. This report and the scarcely less important volume on the Gammaridea contributed to "Das Tierreich" (1906) are Stebbing's best-known works, but a long series of memoirs and lesser papers, extending over more than half a century, contained contributions of fundamental importance on every order of the Crustacea.

Occasional more popular articles and addresses, as well as his "History of Crustacea" (International Science Series, 1893) and the "Naturalist of Cumbrae" (1891), a biography of Dr. David Robertson, give scope for the play of a whimsical and almost boyish sense of fun.

'Scholarly' is the adjective that comes first to the pen in writing of Stebbing's work. Trained exclusively in the disciplines of the older learning and turning to the study of science only in mature life, he brought to it that feeling for antiquity, that sense of the historical perspective of knowledge, which is often wanting in those whose education has been definitely scientific. His erudition seemed boundless, but he wore it with so unaffected a modesty that rash controversialists, less well equipped, were sometimes lured on to their confusion.

Stebbing was elected a fellow of the Royal Society in 1896. He served as a vice-president of the Linnean Society, and later (1903–1907) as zoological secretary. He took a prominent part in the movement for the admission of women to the fellowship of the latter society, and his wife, an accomplished botanist, was one of the first group of ladies admitted. Of the many honours that came to him, none was more valued than the Linnean medal awarded to him in 1908.

Mr. Stebbing died at Tunbridge Wells, where he had resided for many years, on July 9.

W. T. CALMAN.

WE regret to announce the following deaths:

Dr. R. H. Clarke, formerly demonstrator of physiology at St. George's Hospital, London, author of an atlas of sections of the brain of the cat and monkey published in the *Journal fur Psychologie und Neurologie* and joint author with Victor Horsley of a number of papers in *Brain*, on June 22, aged seventy-five years.

M. Albert Frouin, for many years in the physiological research laboratory of the Pasteur Institute, Paris, who has worked on the physiology of digestion, the biochemistry of bacteria, the tubercle bacillus, and particularly the antitubercular action of the salts of the rare earths.

M. Albert Viger, for thirty years president of the French National Horticultural Society, and seven times Minister of Agriculture, on July 8.

News and Views.

DR. A. W. BORTHWICK, formerly lecturer in forest botany at the University of Edinburgh and afterwards serving under the Forestry Commission, was recently appointed to the new chair in forestry at the University of Aberdeen. In his inaugural address, after a preliminary survey of the increasing utility of the products of the forest in supplying many of the everyday needs of the public, and the consequent necessity for the conservation and efficient management of forests, he dealt with the rôle of the university in connexion with the practice of forestry. He considers that a university school of forestry should have three principal aims: (1) To give instruction in the theory and practice of forestry; (2) to conduct research; (3) to advise and assist the owners of forest lands in the management of their woods. "Each of these aims," said Prof. Borthwick, "is important in itself, and not the least important is No. 3. The Department can be of direct help to owners of forests and forest lands, by correspondence, lectures, and personal inspection of woodlands, plantations and lands to be planted. In return the Department is kept in close touch with field problems as they arise, and this is bound to be of use in indicating the kind of instruction to be given to young foresters in training, and also in bringing to notice problems for the elucidation of which further research is required. By concentration on (3) such aims and correlating them into an organised unity, the Department will be kept from going to sleep, a condition only too liable to occur when an overdose of academic forestry is indulged in."

IN the above remarks Prof. Borthwick would appear to be referring to British woods alone. Whilst these are of very great utility for the more elementary portions of the practical courses given to the university forestry student (the future commissioned officer), the latter would be very inadequately equipped for his work, either in Great Britain or out in the Empire forests to which service the greater proportion of the university-trained men go, were the instructor to confine the practical work or his own studies to Great Britain. Prof. Borthwick correctly recognises the importance of this part of the work, and gives an interesting dissertation on the varied branches of forestry education. But his address does not lay stress on the necessity of giving to the future university graduate in forestry practical courses on a far higher plane than anything which Great Britain can provide. To turn out graduates for service either at home or in the Empire (where the demand is far larger) necessitates a continuous study on the part of the staff of the changing conditions and progress (alluded to by the author himself) constantly taking place in the management of the forests of the world. In practice it has been found that only by such means can the forest officer of the future be sent forth with that wide and unbiassed outlook on forestry problems which it is so desirable that he should start with—in so far as it can be implanted in the minds of young men in the all too short space of a university career.

THE Wellington correspondent of the *Times* announces that Dr. Ernest Marsden, assistant director of education, has been appointed permanent secretary of the new Industrial and Scientific Research Department that is being established in New Zealand. This action has been taken on the recommendation of Sir Frank Heath, Secretary of the Department of Scientific and Industrial Research in London, who has recently completed a tour of investigation in Australia and New Zealand. We referred in our issue of May 15, p. 697, to Sir Frank's recommendations for the reconstitution of the Commonwealth Institute of Science and Industry in Australia, and, again, in the issue of July 10, p. 57, to the Bills which have been passed by the Commonwealth House of Representatives to give effect to these recommendations. In introducing the measures, the Prime Minister, Mr. Bruce, referred to the large sums spent on research in public and semi-public institutions in the United States and stated that, for the present, the new Council for Scientific and Industrial Research in Australia will devote its attention to a limited group of problems—liquid fuels, cold storage, and the preservation of foodstuffs, forest products, animal diseases and pests, plant diseases and pests. It is to be hoped that the Council's activities will soon be extended, while the Science and Industry Fund of 100,000*l*., which has been established for providing assistance to those engaged in scientific research and in the training of students in scientific research, should prove an important step towards meeting the very real need in Australia for competent research workers.

THE personnel of the Commonwealth Council for Scientific and Industrial Research has been announced in the Australian House of Representatives by the Prime Minister. The members are: *Executive Committee*: Mr. G. A. Julius (chairman), Mr. W. J. Newbigin, and Prof. A. C. D. Rivett. *Chairmen of State Committees*: N.S.W., Prof. R. D. Watt (Agriculture); Victoria, Sir David Orme Masson (Chemistry); Queensland, Prof. H. C. Richards (Geology); South Australia, Prof. T. Brailsford Robertson (Biochemistry); Western Australia, Mr. B. Perry (Manufacturing industries); Tasmania, Mr. P. E. Keam (Agricultural and stock-breeding industries). *Co-opted Members*: Prof. E. C. Goddard, Queensland (Zoology and botany), Prof. H. A. Woodruff, Victoria (Veterinary pathology). The Council held its first session on June 22-25, and adopted general plans for work during the next twelve months. Its proposals apply chiefly to primary industries. As was foreseen by Sir Frank Heath, the operations of the Council will be hampered for some time by the lack of a supply of highly trained young investigators. Assistance will be sought from abroad, and extensive plans are being put into effect for sending promising Australian graduates to England and the United States for special training.

THE radio communication Bill, which was to regulate the use of radio in the United States, failed to pass

Congress before the long vacation. During the next six months, therefore, there is a risk of serious confusion in broadcasting development in the States. The Department of Commerce has allotted 89 wave-lengths to 528 stations, and there are 650 further applications for station licences awaiting consideration. Now, however, they are left without authority either to grant or to refuse any application. The Secretary of Commerce, Mr. Hoover, has hitherto been regulating all transmission mainly through a 'gentleman's agreement' with the broadcasters themselves. The Bill discussed in Congress expressly declared that it was the intention of the Federal Government to preserve the channels of radio transmission as "perpetual mediums under the control and for the people of the United States." Licences are limited to two years and are not available to aliens or to any applicant "who has been convicted of monopolising or attempting to monopolise the radio business." Broadcasting is apparently becoming very profitable as an advertising medium in the United States. According to the *Times* of July 27, so much as 50,000*l*. has been offered for the transfer of a licence. Licences were recently issued in Chicago to the Moody Bible Institute and the Chicago Federation of Labour. To farmers in the United States broadcasting has proved to be a great boon. Mr. Pickard, the radio officer of the Department of Agriculture, has stated that broadcasting is doing more for the farmer than any other single contribution of science during the century. Farmers living so far as 60 miles from a railway have been induced by radio lectures to change their methods of farming to more profitable systems.

ALTHOUGH windmills have been in use for more than a thousand years, yet accurate data as to their efficiency cannot easily be obtained. The Institute of Agricultural Engineering of the University of Oxford has therefore made a useful contribution to our knowledge of the subject by publishing a report on the use of windmills, more especially for the generation of electricity. A windmill experimental station was erected on the Annables estate, midway between Harpenden and Luton. The field slopes south-westward towards the Dunstable road, and seven windmill plants of various types have been erected on it. The site is a good one, as it obtains the benefit of unrestricted winds from all directions. Full results of the economic, technical and meteorological observations extending over a period of one year are given. The cost per electric unit utilised varied between 12·7 pence and 4·0 pence. By using improved wheels the cost of production for the smaller and more inefficient mills could be reduced by 30 or 40 per cent. Considering the very small dynamos used, having an output of only a few horse power, these results are quite satisfactory. Some of the plants begin to operate when the wind attains a velocity of about six miles per hour and cease operating when the velocity falls to five miles per hour. The output increases more rapidly than the velocity of the wind. The results prove that, in districts remote from a public electric supply, small windmill power schemes might prove useful and economical. Those who already own an engine-generating set and desire to supersede or supplement it should consider adopting wind power. It is also to be remembered that on higher sites than Harpenden or on districts nearer the coast better results would probably be obtained. In Denmark and Germany considerable use is made of wind power in generating electricity.

ALTHOUGH it may be pleaded that a state of chaos in human undertakings has a certain evolutionary value, as being indicative of potential progress, the complexity of civilised life nevertheless necessitates the logical classification of a vast amount of important information as a condition of ordered progress. Bibliographies of scientific and technical literature come well within this category, and their number is constantly increasing. Collective indexes are indispensable to the scientific worker, and although they are very costly to produce, the labour and expense involved in their production cannot be obviated. Bibliographies of general subjects are less essential and have been comparatively neglected, hence we welcome the publication of "A Bibliography of Research" by the National Research Council of the United States, a small volume containing about 800 references to articles on research that have appeared in scientific, technical and trade journals during the years 1923, 1924 and 1925. To facilitate reference, the material has been subdivided into forty classes, a difficult task which has involved a considerable number of duplicate entries; thus four of five references to the National Physical Laboratory given under the heading 'Physics' are repeated in full, and with different index numbers, under the heading 'Research—General: Laboratories.' The bibliography might also be criticised from the point of view of completeness, to which, however, no claim is made. Thus only one of the annual reports of the Committee of the Privy Council for Scientific and Industrial Research is included; and there are very few references to German (11) and French (18) literatures, whilst other continental countries appear to have been neglected. Although criticisms of this kind are not difficult to make, the publication will undoubtedly be most useful to all interested in the general subject of research, and the National Research Council is to be congratulated upon its production.

IT is gratifying to note that anthropological investigations in Canada continue to be actively prosecuted under official auspices. The report of the Department of Mines for the fiscal year ended March 25, 1925, which has just been issued, contains a report of the Victoria Museum covering the work of the anthropological and the biological divisions. Apart from the work of cataloguing, arranging, and preserving specimens, the anthropological staff has been engaged on a number of field expeditions. Mr. Harlan I. Smith visited the Bella Coola Indians of British Columbia, Mr. C. M. Barbeau was engaged among the Gitksan Indians of British Columbia, Mr. D. Jenness continued his work of the previous fiscal year among the Carrier and Sikani Indians of British Columbia, and Mr. F. W. Waugh visited the

Montagnais Indians of the Lower St. Lawrence, whence unfortunately he did not return, as he disappeared mysteriously after visiting an Indian reservation in September 1924, and has not since been traced. A large number of specimens, photographs, and phonograph records were added to the Museum collections as a result of these expeditions, and records and studies of specific subjects under observation have appeared in various scientific journals.

THE growth of the regional survey movement as the geographer's special field of research and contribution to our knowledge of Great Britain has been marked in recent years. The Geographical Association in helping to foster this movement has published in the *Geographical Teacher*, vol. 13, No. 75, a list of libraries, museums, universities, and societies which have in their keeping or are undertaking surveys for their respective areas, also a long list of actual surveys and a list of civic surveys that have been published. The Association also hopes to make a special collection in its lending library of works and bibliographies dealing with special regions. A bibliography of Hertfordshire is published as a specimen. The lists given in the present number do not claim to be exhaustive, and will be added to from time to time as more information is sent to the Secretary of the Regional Survey Committee, Geographical Association, Marine Terrace, Aberystwyth. Some useful suggestions are also made for uniform systems of registration on maps.

AT a representative meeting held in March last, it was resolved to found an Institution of Fuel Technology, and a committee was appointed to prepare a constitution. A further meeting was held on July 30, when the draft constitution was formally adopted and the following officers were elected: *President*—Sir Alfred Mond, *Vice-Presidents*—Lord Aberconway, Prof. H. B. Dixon, Sir Robert Hadfield, Bart., Lord Weir, and Mr. D. Milne Watson; *Council*—Mr R. A. Burrows, Sir Philip Dawson, Dr. F. A. Freeth, Sir William Larke, Dr R. Lessing, Mr M. Mannaberg, Sir Edward Manville, M.P., Mr. S. McEwen, Lord Montagu of Beaulieu, Sir Richard Redmayne, Admiral Sir Edmund Slade, Mr Wallace Thorneycroft, Dr M. W. Travers, Prof. R. V. Wheeler, Mr. W. A. Woodeson, Mr. G. R. Thursfield, Mr. T. Hardie, Mr. A. H. Middleton, and Mr. W. M. Selvey; *Hon Treasurer*—Sir William B. Peat; *Hon. Secretary*—Mr. Edgar C. Evans, Caxton House (East), Tothill Street, S.W. An autumn or winter meeting for the discussion of papers is to be arranged.

A RATHER severe earthquake, strong enough to throw down a few chimneys and to fissure buildings, was felt in Jersey on July 30 at 2.18 P.M. In France it was felt at St. Malo and Rennes; in England, at Bournemouth and other places on the coast of Sussex and Hampshire. In strength and area of disturbance, it closely resembles two others that have visited the same district during the last half-century. The earlier of these, on January 28, 1878, disturbed an area of about 68,000 square miles, including Havre, Rouen, and Paris, as well as London, Bovey Tracey, Brighton, and St. Leonards. Its centre lies probably a short distance to the east of Jersey. Again, on May 30, 1889, another, and stronger, shock was felt over about the same area, and originated in or close to the same focus.

THE meeting of the British Association at Oxford in 1894 is probably best remembered as the occasion on which Lord Rayleigh and Sir William Ramsay, who have both since passed away, announced the discovery of the new gas argon in the atmosphere. In an article in the August issue of *Discovery*, Sir Oliver Lodge gives some reminiscences of the meeting and makes it clear that it should also take its place in the history of radio-telegraphy. At that time, Hertz had recently died and as a memorial to him Sir Oliver had repeated some of his experiments on the transmission of electromagnetic waves at the Royal Institution, using the Branly iron filings coherer and galvanometer as receiver, instead of the original point coherer and telephone. These experiments were shown again at the British Association meeting, and long and short signals corresponding to the Morse code were transmitted through the air from a neighbouring room to the large lecture theatre of the Oxford Museum, where they were demonstrated to an enthusiastic audience by the aid of a Kelvin mirror galvanometer.

WE have recently received from Prof. S. A. Forbes, Chief of the Natural History Survey Division of the State of Illinois, a reprint of a paper entitled "The Lake as a Microcosm," originally read and published in 1887. This paper, of some fourteen pages, was reprinted many years ago, but has long been out of print. The descriptions of conditions—physical and faunistic—apply especially to the lakes of Illinois, and the paper has therefore been much used by the students in the State University, while reference to problems of general interest has led to a demand for it also elsewhere, and to its reissue in the *Bulletin of the Natural History Survey* (vol 15, article 9).

THE Ministry of Agriculture and Fisheries has recently republished its various leaflets on "Insect Pests of Farm and Garden Crops" in collected form as Section Volume No. 11. Altogether twenty-seven leaflets are reprinted and they form a volume of 111 pages, including introductory remarks on the general principles underlying the application of control measures The production of these leaflets has greatly improved in recent years, and the illustrations are of a higher standard. The information concerning the habits and methods of combating different pests is trustworthy and up-to-date, the results of recent research being incorporated in easily understandable language. There is no doubt that many growers will welcome the appearance of so much practical information in a form more convenient than that of separate leaflets, which are easily lost unless systematically filed. The low price of 1*s*. 3*d*. (post free) should bring the volume within reach of all who are likely to benefit by consulting it. It is obtainable from the Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1.

THE "Statistical Report of the Health of the Navy for the Year 1923" is presented by the Director-General, Surgeon Vice-Admiral Sir Joseph Chambers, K.C.B., and issued by H.M. Stationery Office (5s. net). The returns for the total force (89,100) show a marked improvement in the general health of the British fleet compared with the previous two years, the case, invaliding and death ratios all showing a decrease. This is doubtless largely due to the preventive measures now adopted. Health lectures are given by medical officers, and the men are warned of the risks they run in drinking polluted waters, eating raw vegetables and salads, oysters and other shellfish, and the rôle of flies in the spread of disease is explained. All water taken for drinking and cooking from the shore is chlorinated, and all fresh milk used, unless the source is well known, is sterilised. The excreta of all enteric patients are examined during convalescence on three occasions at monthly intervals, so as to eliminate carriers. All officers and men detailed for the Mediterranean, East Indies, and China stations are inoculated against typhoid and paratyphoid fevers before leaving England.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A public analyst for the borough of Northampton—The Town Clerk, Guildhall, Northampton (August 16). An assistant lecturer in agricultural zoology at the North of Scotland College of Agriculture—The Secretary, 41½ Union Street, Aberdeen (August 19). Lecturers in agriculture, botany, and entomology and zoology at the Imperial College of Tropical Agriculture, Trinidad—The Secretary of the College, 14 Trinity Square, E.C.3 (August 21). An assistant lecturer in electrical engineering at the Royal Technical College, Glasgow—Prof. S. Parker Smith, Royal Technical College, Glasgow (August 23). A research assistant for work in connexion with colliery wire ropes, and a junior research assistant for work on materials and structures used for the support of underground workings—each under the Safety in Mines Research Board—The Under Secretary for Mines, Establishment Branch, Mines Department, Dean Stanley Street, S.W.1 (August 25). A technical officer for design of wireless apparatus for service aircraft and aerodrome use—The Superintendent, Royal Aircraft Establishment, South Farnborough, Hants (August 28, quoting No. A.121). An instructor in bee-keeping in the department of Agriculture of the University of Leeds—The Registrar (August 28). An assistant in the botany department of the University of Aberdeen—The Secretary (August 30). A head of the Department of Industrial Administration and a lecturer in the same subject at the Manchester Municipal College of Technology—The Registrar (September 20).

Our Astronomical Column.

SUNSPOT ACTIVITY.—Of the two naked-eye spots, Nos. 7 and 8, which were on the sun's disc together during the last week of June, the first had entirely disappeared when its position came again into view, and the second had diminished to a relatively small spot. A new group of considerable size has, however, been seen recently in transit across the disc and was a conspicuous naked-eye object to those observers who habitually watch these large spots. In a refracting telescope of 3 or 4 inches aperture, much interesting detail could be seen in the penumbral filaments. In type the group conformed fairly closely to that of a 'normal' stream, with a well-defined circular leader, a composite follower 12° in longitude behind, and a cluster of small unstable spots between. The axis of the stream was inclined about 15° equatorwards Both the leading and following spots were large enough to be visible separately to unaided vision, especially on July 29, when their separation of 12° solar longitude was equivalent to nearly 4′

The latitude of the group should be noted. Hitherto, no important group has appeared this cycle so near the sun's equator. In previous cycles, the first very large spots in latitudes so low as 10° have occurred about two years before the respective maxima. Data of position and area (expressed as a fraction of the sun's hemisphere) of the recent spot are as follows:

No.	Date on Disc.	Central Meridian Passage.	Latitude.	Area.
9	July 24-Aug. 5	July 30·0	11 S.	1/550

NAMING OF MINOR PLANETS.—The three planets that commence the second thousand have received names that recall the circumstances of the discovery of Ceres, the first member of the family, about a century and a quarter ago (*Astr. Nach.* No. 5454). Number 1000, discovered by Reinmuth, has been named Piazzia, after the discoverer of Ceres; 1001, discovered by Beljavsky, has been named Gaussia, after the calculator of Ceres' orbit; and 1002, discovered by Albitzky, has been named Olbersia, after the detector of Ceres at its second opposition. These appropriate names were given by Mr. B. Asplind of Karlstad, Sweden, with the consent of the discoverers.

LUNAR AND PLANETARY TEMPERATURES.—The results of an investigation of planetary temperatures by Menzel, Coblentz and Lampland by means of the radiation transmitted through a water cell, are described in the *Astrophysical Journal*, vol. 63, p. 177. The theory of the method has previously been given by Menzel (*Astroph. Journ.*, vol. 58, p. 65), and rests on the fact that the solar energy reflected from a planet is of short wave-length, whereas the radiated planetary energy is of much longer wave-length. The water-cell transmission gives a measure of the ratio of the short-wave solar energy to the total energy, and hence of the amount of planetary radiation which is able to pass through our atmosphere. This atmospheric transmission depends on the spectral distribution of the radiation, and therefore, finally, upon the planetary temperature. The results of the latest work seem to show that the temperature of Mars may reach 10° C. at perihelion, but with large diurnal fluctuations (the night temperature being probably below −85° C.). The bright areas on Mars appear to be at a lower temperature than the dark areas, and the temperature of the south polar cap ranges from −100° C. to −15° C., suggesting ice or snow as a possible cause. Some results are also given for the moon, Venus, Jupiter, Saturn, and Uranus. There seems to be no evidence of internal heat in any of the giant outer planets.

Research Items.

Royal Costume and Race in Ancient Egypt.—In *Ancient Egypt* for June, Miss M. A. Murray examines details of the dress of kings of the early dynasties of Egypt and suggests that certain inferences bearing upon cultural origins may be drawn from the results. On the slate palette of Narmer, the king is shown wearing a belt at the back of which is an animal's tail with long rippled hair—a bull's tail. Sir Flinders Petrie has pointed out that the bull's tail was a promoter of fertility. While the king was typified by two creatures, the falcon and the bull, he was more truly falcon. The falcon Horus conquered the country, but his religion was exotic, belonging to the king only. Egypt was and remained a cattle-worshipping country, and therefore the king had to become a bull. This was accomplished by a ceremony in which the outward and visible symbol, the bull's tail, was attached to his person. The Sed festival was connected with the tail of the king; but Prof. Newberry has suggested that this was a marriage ceremony. In Crete, when bull-worship was introduced, the queen, through whom, as in Egypt, descent was transmitted, was disguised as a cow for the celebration of the Sacred Marriage with the bull. In Egypt the Sed festival may represent the making of the foreign falcon into a bull at the time of the marriage to the queen of the bull-worshippers. The royal head-dress may suggest the provenance of these rulers. The crowns appear to be turbans. The Red Crown of Lower Egypt is of a form now worn by the Marwaris of Rajputana. This head-dress in Egypt is worn only by the king and by foreigners. It is indigenous in Asia and especially Persia and northern India. The connexion between early Egypt and Elam is established and, in view of the connexion between India and Sumeria, it is possible that there may have been a common centre influencing Egypt.

The Last Forest Phase in Britain.—Mr. O. G. S. Crawford in *Man* for July discusses the implication of certain conclusions of geologists and meteorologists which bear directly upon archæology. From 3000 B.C. until 1800 B.C. the climate of Britain was drier than at present. Further, the land stood 60 feet higher than at present, with forest and fen in the area now the North Sea, and forests on the southern and western coasts. This last forest phase may be equated roughly with the British neolithic period, which has two stages, an earlier with no pottery and no agriculture, and small implements, many resembling palæolithic types, and a later, megalithic, stage, with agriculture and many surviving implement-types which show little change. There is no evidence that the people of the first stage are descended from our palæolithic population, and it is possible that they spread across the fen, which is now the North Sea, from Denmark. On the other hand, the megalith builders were a distinct people. The distribution of megaliths arranged in order of development suggests an eastward migration. This is supported by the legendary connexion of Stonehenge and Ireland and the Irish character of Middle Bronze Age pottery in Pembrokeshire. In eastern Wales and in England south-east of the Severn and south of the Humber, later types of megaliths preponderate over the earlier. This suggests, therefore, that an eastward migration occurred at the close of the dry period when the west was becoming appreciably more moist and difficult for agriculture. Were climatic conditions also responsible for the departure of the megalith builders from their homes in France and Spain?

Winter Climate and the Incidence of Pulmonary Tuberculosis.—The view has been expressed that the poor ventilation of houses consequent upon a rigorous winter climate may be an important factor in the causation of pulmonary tuberculosis. Thus, the higher incidence of phthisis in Sweden compared with England and the high incidence of the disease among the Esquimaux have been attributed to the influence of this factor. J. R. Miner has subjected this hypothesis to examination (*Amer. Review of Tuberculosis*, vol. 13, No. 4, 1926, p. 366), taking as his data the mortality statistics for the white population of the United States Registration Area, which covers a wide range of climate, yet refers to a population fairly homogeneous racially, and highly homogeneous in customs and social environment. The death-rates from tuberculosis of the lungs and acute miliary tuberculosis in the various registration States have been grouped according to January mean temperatures. After the application of various corrections, the result emerges that the white death-rate from pulmonary tuberculosis in the United States is higher in those States with a mean January temperature between 30° F. and 40° F. than in colder or warmer regions. No evidence is found to support the view that severe winter climates, or poor ventilation resulting therefrom, are important factors in the etiology of pulmonary tuberculosis.

Scottish Sea Trout.—Mr. G. H. Nall gives us interesting information on the sea trout of the River Ewe and Loch Maree (Fishery Board for Scotland Salmon Fisheries, 1926, No. 1. (Edinburgh and London: H.M.S.O., 1926.) 4*s*. 6*d*. net), as a result of measurements and scale readings of a very representative number of fish, 1512 in all. Included among these are examples representing the hatches of 12 consecutive years, 1912–1923, fish ranging in size from 3 oz. to 10 lb. and in age from $2\frac{1}{2}$ years to 13 years. Nearly three-quarters of these undertook their smolt migration after three years' river life, thus tending to confirm the theory that length of parr life depends on food supply, northern streams having comparatively low food resources, which leads to long parr life. The record of two fish remaining as parr for six years is interesting, being the first such case recorded for the British Isles. Of the Ewe trout, the scales of which showed spawning marks, 48·8 per cent. spawned for the first time in the second winter after smolt migration and 40·6 per cent. in the third winter. The main runs begin in mid-July and last until autumn. The great majority of fish spawned in successive years. The oldest fish in the collection had spawned eight times and was thirteen years old. In condition, as measured by the standard *K*, these sea trout were good. Sea trout have previously been studied in the River Forth by Menzies and the River and Loch Hope by Nall, who, in this paper, makes interesting comparisons between the fish from the various regions.

Studies in De-differentiation.—Prof. J. S. Huxley has described reduction phenomena in *Clavellina lepadiformis* (*Pubblicazioni della Stazione Zoologica di Napoli*, vol. 7, 1926), in which he confirms Driesch's discovery that whole individuals of this species will undergo de-differentiation or reduction as readily as pieces of the animal. Examination of some of the morphological changes occurring during the process shows that the pharynx and atrium are reduced much more rapidly than any other organs. The nervous system passes through a stage in which the anterior portion is hollow. The heart remains differentiated and active for a long period, but is

finally suddenly reduced to a mass of de-differentiated cells. The gonads may be represented at a late stage by a single hollow vesicle. The digestive loop usually remains very little changed until late stages. The atrium may be converted into two separate vesicles by the breaking and subsequent resorption of its dorsal cloacal portion. The epicard is relatively resistant, and in advanced stages of reduction shows horn-like processes which may be attached to the peribranchial cavities. Some organs may disappear, apparently by cell-migration The view is put forward that the changes cannot be supposed to represent reversions to stages passed through in embryogenesis. The resemblance to such stages is accidental, and is brought about chiefly by mechanical means.

SPERMATOGENESIS IN SPIDERS.—In a paper on the spermatogenesis of the spider, *Tegenaria domestica* (*Bull. Internat. de l'Acad. Polonaise des Sci. et Lettres*, Série B. No. 3-4), Mme. Julia Sokolska shows that the number of chromosomes in the male is 18 pairs, together with an unpaired heterochromosome or X-chromosome composed of three equal bodies, which are separate during meiosis, but all usually pass to the same pole in the reduction division. The two resulting types of sperm can be identified by the visible presence or absence of these three bodies from the spermatids. Abnormal cases were found, however, in which two of the three elements of the X-chromosome separate from the third in the heterotypic division, as well as cases in which four such bodies were present. These clear-cut results contrast in some respects with those of Dr. E. Warren (*Annals of the Natal Museum*, vol. 5, part 3) on the habits, oogenesis, and early development of a South African spider, *Palystes natalius*. After describing the spinning of the egg-sac and the 'psychological behaviour,' a detailed description of the egg development is given. The author falls readily into the old snare of amitosis, and his observations on this head are unconvincing. In the maturation of the egg two polar bodies are formed, but the second is retained within the egg. The author admits that these divisions are mitotic, but in the five cases observed the chromosomes 'averaged' 10 for the first polar body and 9 each for the second polar body and the egg nucleus. Chromosome counts are now, however, of little value unless they are exact. It is to be hoped that an effort will be made to get more precise results

STUDIES ON A PARASITE OF THE HESSIAN FLY.—C. C. Hill contributes (*Journ. Agr. Res.*, Washington, vol. 32, No. 3, 1926) an account of *Platygaster hiemalis*, one of the most widespread and effective parasites of the Hessian fly in the United States. In the eastern wheat-growing regions, this Hymenopterous parasite kills annually from 16 to 40 per cent. of the autumn generation of the fly. The eggs are deposited in the egg of the fly and develop polyembryonically (by twinning) or monembryonically; the resulting yield in adults is about a 50 per cent. increase over the number of eggs deposited. The larva consumes the contents of the host, but the latter, before succumbing, usually succeeds in forming a puparium. Within this the cocoons of the parasite are formed, and an average of six adult parasites emerge from each host. The adult is about 1 mm. long, very active, flies readily, and is positively phototropic. The female is able to reproduce parthenogenetically, and impregnated females usually deposit both fertilised and unfertilised eggs at each oviposition. Approximately 66 per cent. of the adults are females. The female lays from one to eight eggs at a time, and shows marked ability to recognise eggs of the fly in which she has already oviposited. In one instance a female, crawling over a leaf which bore 42 eggs of the fly, oviposited in 24 of these in fairly regular order on the first tour; on the return she brushed all the eggs with her antennæ and attacked two that had not previously been pierced, but only one of those previously visited was pierced a second time. Females have been observed to examine with their antennæ the area on a wheat leaf from which the egg of the Hessian fly had been removed, and even to attempt to oviposit thereon. It would appear that chemotropism plays an important part in the location of the host egg. *Platygaster hiemalis* passes the winter and early spring in the embryonic stage; by the end of August the adults are ready to emerge from their cocoons during the oviposition period of the Hessian fly in the fall of the year.

WEST INDIA HURRICANES.—An important publication upon the hurricanes of the West Indies has been issued by Father Sarasola, Director of the newly organised National Observatory of Colombia ("Los Huracanes de las Antillas." Notas Geofisicas y Meteorologicas Num. II., Bogota, 1925). In addition to marshalling a large number of facts about these destructive visitations, he discusses methods of forecasting and reviews current theories regarding the origin of tropical cyclones. It is pointed out that whereas the cyclones of temperate latitudes are most severe in winter when 'polar front' discontinuities of temperature and humidity are sharpest, tropical cyclones are most active in the warmest season. The view is favoured that tropical cyclones are fundamentally connected with the conflict of air currents, and in this connexion it seems a pity that the author appears to overlook what is really very convincing evidence that this view is correct. Tropical cyclones occur mainly in late summer and autumn towards the margin of the tropics on the western sides of the oceans in both hemispheres, precisely when and where one Trade system having crossed the equator encounters currents from the opposing Trade system, the one exception to the rule being the South Atlantic, which is hurricane-free in the absence of a seasonal migration of the North-east Trade across the equator. This is the significant geographical background of tropical cyclones, and should be observed by all writers who investigate the structure of these storms in detail. Whether there is anything corresponding to the 'discontinuities' of temperate latitude cyclones on 'polar front' principles is not yet clear, but it is likely that there are considerable differences of humidity, if not of temperature, between the opposing currents feeding a tropical hurricane. Father Sarasola's work contains much local detail in relation to the storms of the Caribbean Sea; the wider influences bearing on the subject are not neglected, a good deal of attention being given to solar activity in relation to the weather.

WIND AND SPEED OF WAVES.—In a paper entitled "Observations of Wind, Wave and Swell on the North Atlantic Ocean" in the *Quarterly Journal of the Royal Meteorological Society*, vol. 51, No. 218, Dr. Vaughan Cornish records his observations on the relationship between velocity of wind and waves. He found a close agreement between the wind and the velocity of the waves under the conditions of the final stage reached after a prolonged wind. The discrepancies between the two figures which were apparent in some observations were almost entirely due to swell. A crossing swell effects considerable reduction in the speed of the waves, a concurrent swell little reduction in speed and a diminution in height of the waves. When two sets of swell cross

the waves, their effects in reduction of wave speed are additive. This would explain the rapid rise of waves with wind on large lakes and inland seas when there is little swell to hamper the wave-making action of the winds. Dr. Cornish gives his figures in full and describes the methods he devised to measure the velocity of the wind.

SUBSIDENCE OF KILAUEA VOLCANO.—A rough estimate has been made of the total volume of subsidence of Kilauea during the years 1921–24 (*Volcano Letter*, No. 74, May 25, 1926). At Halemaumau the amount of subsidence in this interval was 13 or 14 feet, and at a distance of twenty miles to the north-east it was little more than an inch. Assuming that the subsidence was symmetrical about Halemaumau as a centre, the total volume of subsidence would be about one-seventh of a cubic mile.

COLOURS DUE TO IRON IN MINERALS AND ROCKS.—In the *American Journal of Science* for July 1926 Mr. G. R. MacCarthy presents the results of a comprehensive study of the colours produced in rocks by various types of iron compounds. It is shown that the natural yellows, browns and reds are due to the presence of ferric compounds. Hydrous ferro-ferric minerals are blue in colour, and are responsible for the blues frequently exhibited by clays and shales. The suggestion that these tints are produced by disseminated organic matter is refuted. Greens are considered to be the result of mixtures of iron-blues and iron-yellows, for no evidence of the existence of any single green compound has been found. The chocolate-red of hæmatite sometimes approaches purple, but the true purple colours of shales and slates are ascribed to mixtures of iron-reds and iron-blues. Anhydrous ferro-ferric compounds produce only greys and blacks, like the carbonaceous matter that is generally present in black argillaceous rocks. The rôle of iron as an inorganic colouring agent has thus been rationally extended over the whole range of colours found in sediments.

CONTRASTED TYPES OF MUD-CRACKS.—Continuing his valuable work on the structural features of sediments, Mr. E. M. Kindle has published and described a most instructive suite of photographs of various types of mud-cracks (*Trans. Roy. Soc. Canada*, 20, sec. 4, 1926, p. 71). A series from the playas of north-western Nevada shows polygonal shrinkage cracks (*a*) with flat tops, (*b*) with curled-up edges, (*c*) with rounded margins, and (*d*) with a reticulation of small polygons within the larger ones. The curling-up tendency is associated with the presence of abundant colloidal matter in the clay, while the downward rounding of other mud-cracks indicates a notable percentage of sodium chloride in the material undergoing desiccation. Another series of desert mud-cracks shows a number of radiating rosette-like fissures, due probably to convection currents in the oozy mud during the initial stages of desiccation. In another type, from Jervis Island in the Pacific and from Southern Australia, the ordinary polygonal cracks are not open fissures, but are outlined by narrow ridges composed largely of alkali sulphates and other salts. It is thus clear that the muds of saline lakes, fresh-water lakes and the sea-shore, develop shrinkage cracks of sharply contrasted types, and the recognition of similar features in older sediments may therefore provide valuable evidence bearing on the origin of the latter, and particularly of continental facies of sediments.

RANGE OF α-RAYS OF THORIUM C + C′.—Experiments with a modified form of the Wilson cloud apparatus, enabling a large number of photographs to be taken one after another under conditions which made it possible to measure the range of the α-rays accurately, are described by Fraülein L. Meitner and Herr Kurt Freitag in the *Zeitschrift für Physik* of June 16. Altogether three thousand photographs were taken. Thorium C breaks up partly into thorium C′ with emission of a β-particle and partly into *C″* with emission of an α-particle, the mean range of the latter being 4·8 cm. Thorium C′ sends out an α-particle with mean range 8·6 cm. and gives thorium lead. The ratio between the numbers of these two classes of α-particles was determined by counting to be 34·3 : 65·7, which agrees well with the value obtained by Marsden and Barratt using the scintillation method. The ranges in different gases were determined and the mean relative braking power of these gases calculated. The variations of the range on either side of the mean were determined in the different gases and compared with the values deduced by Bohr from the classical theory; good agreement was found. The existence of a group of α-rays with 11·5 cm. range in air discovered by Rutherford and Wood was confirmed and a new group with 9·5 cm. range was found. There were on the average 200 of the 11·5 cm. range particles and 70 of the 9·5 cm. range to 10^6 ordinary thorium C′ α-particles The existence of α-particles of greater range than 12 cm., announced by Bates and Rogers has not been confirmed; particles with longer range than this are clearly shown to be hydrogen rays.

DRAWING INSTRUMENTS.—Among other sets of instruments manufactured by Messrs. Harling, 117 Moorgate, London, E.C 2, at their new factory in Upper Clapton is a wallet case, B.E. 114, which we have had the opportunity of testing. This case contains a 4½-inch divider with hair spring adjustment and movable needles; 3-inch bow pen compass and a bow pencil compass of the same size, both instruments having double knee joints, while the ink point of the pen is made of stainless steel. All these instruments are made of hand-drawn electrum; the head joints work on steel cones and are fitted with a device for maintaining the handle upright. The case also includes a set of three spring bows, the steelwork of which is made of stainless steel; these instruments have central screw adjustments, and are both light and rigid in use. There are also a 6-inch drawing-pen, made of stainless steel with a lift-up nib permitting of cleaning and instantaneous resetting to the same width of line, and another 6-inch drawing-pen, also of stainless steel, but without the lift-up arrangement. A pricker is included. All the above described instruments are thoroughly well made; the design is good and the instruments are suitable in a high degree to the work of an engineer's drawing office. The last instrument in the case is a portable beam compass with divider, pen, and pencil points. The duralumin beam of this instrument is made in three lengths with push-in joints, and makes up to 29½ inches. The travelling heads are driven by means of milled rollers. The section of the beam is wedge-shaped, and each head has a spring which presses the head into the wedge and also presses the roller against the top side of the beam. The design is good, the heads move easily, and are rigid whilst circles are being drawn. Unfortunately, sufficient care has not been taken in manufacture to get all three bars of exactly the same cross-sectional dimensions; two of the bars in the set submitted for examination are very good in this respect, and the heads pass easily over the joint of these bars. The other joint is bad owing to the defect mentioned, and the head requires assistance to pass the joint.

Kammerer's Alytes.

(1) By Dr. G. K. NOBLE, American Museum of Natural History, New York, N.Y.

THERE is in existence, resulting from the much-discussed experiments of Kammerer (1919, *Archiv. f. Entwicklungsmechanik*, 45, pp. 323-370, pls. x.-xi.), only a single specimen said to show the modifications described by him. This specimen is preserved in the Biologischen Versuchsanstalt, Vienna, and is the one which Kammerer recently brought with him to England and used to support his contention that he had produced heritable modifications in the midwife toad (Kammerer, 1923, NATURE, 112, pp. 237-238).

Although this specimen had presumably been carefully studied in England—for Kammerer (*loc. cit.* p. 237) claims: "Dozens of scientific men have seen the pads and are now convinced"—a preliminary examination of it by me in Vienna revealed such unexpected features that Dr. H. Przibram and I have found it advisable independently to make a thorough macroscopic, histological and chemical examination of the critical features of the specimen.

It will be remembered that Kammerer claimed to have produced heritable nuptial pads in a batrachian which normally lacks them. I found the specimen to have its left manus blackened both on its dorsal and ventral surfaces, the extent of the darkened area being fairly well shown in a photograph of the specimen made in Cambridge (Kammerer, 1924, "The Inheritance of Acquired Characteristics," New York, Fig. 9). A slight blackening was also to be seen on part of the right manus. Neither manus had the appearance of possessing nuptial pads, but both seemed to have been injected with a black substance, for the blackening included some of the capillaries.

An examination of the blackened areas under moderate magnification with a binocular microscope revealed that the colouring was not epidermal; that is, in epidermal spines, but in the derm. No trace of spines, points, brushes or other asperities could be seen on the integument of the prepollex, or surrounding region of either hand. The left wrist of the specimen had been lacerated. A slight pushing aside of the muscles revealed that the ventral wrist muscles and part of the palmar muscles were surrounded by a black colouring matter on all sides. This substance was in such abundance that it readily washed out in the dissecting dish water which filled the spaces between the exposed muscles. It was clear that these blackened areas were not nuptial pads; that is, patches of pigmented asperities, for the epidermis was not thrown into spines. Further, the colouring matter was not epidermal, but was distributed in great masses under the skin, between the muscles, and even in many of the capillaries on both dorsal and ventral surfaces of the left manus.

Dr. Przibram and I have independently made sections of the integument from the prepollex region of the left manus of the specimen under discussion. This is the region which in the water-breeding Salientia most frequently bears asperities. It is at the base of the first finger. Further, it was the region of maximum blackening in Kammerer's specimen. Although the specimen was poorly fixed, the epidermis in this region was intact, except along one edge where it was beginning to be shed. No suggestion of asperities are visible in my sections. The surface of the epidermis is perfectly smooth. The black colouring matter is seen to lie in great masses in the derm and among the muscle fibres, while some of the capillaries are choked with the same substance. It is therefore clear that no modifications occur in the prepollex region of Kammerer's specimen, other than those produced by poor fixation and the black substance. Dr. Przibram has confirmed from his own sections my observations that no suggestion of asperities are present in this specimen.

The black substance, so irregularly distributed through the muscles, has the appearance of India ink, for under the highest powers the granules are black, not brownish black (or lighter) as most amphibian melanins. However, a critical test as to the nature of this substance is necessarily a chemical one. Oppenheimer (1909, "Handbuch der Biochemie des Menschen und der Tiere," Jena), in describing the properties of melanin, states that it may be changed into a lighter-coloured substance by treating it with concentrated nitric acid. Further, this product is soluble in alkalis. I have carried out a series of experiments with different kinds of amphibian integuments, some injected with India ink, and others merely fixed in alcohol or formol, and have found the test to be critical in distinguishing melanin from India ink. With Dr. Przibram's permission I removed a piece of integument from the palm of Kammerer's specimen at the base of the second finger. A large mass of black substance adhered to the dermal portions of the skin. The piece was cut into three parts and each treated for different periods, first in concentrated nitric acid, and after washing, in concentrated ammonium hydroxide. In spite of this variety of treatment, known to be critical in all cases, the black colouring matter remained intact, while the few small and widely separated melanophores readily observable under the binocular, disappeared. In this resistance to the treatment the colouring matter resembled the India ink masses in our controls. Dr. Przibram has carried these experiments further, and writes: "The black substance has also been subjected to the treatment with antiformin and withstood this reagent, which dissolves all melanins known to now" We may conclude that the substance which gives the dark appearance to the left manus of Kammerer's specimen is not melanin.

It has therefore been established beyond the shadow of a doubt that the only one of Kammerer's modified specimens of Alytes now in existence lacks all trace of nuptial pads. The question remains: Might not this specimen at one time have possessed them? There are available three kinds of evidence bearing on this point: (1) sections said to have been made from the pad of the modified specimens; (2) photographs showing more or less clearly some indication of the pads; and (3) testimony of observers who believe they saw asperities in the modified specimen.

Kammerer (1919, *op. cit.*, Pls. x. and xi.) has produced figures of histological preparations said to be made from the nuptial pad region of his specimens, or to be more exact, (translation) "through the skin of the first (inner) finger." Similar preparations were sent by Dr. Kammerer some time ago to Dr. E. Uhlenhuth, who has kindly loaned them for examination. Further, other microscopical preparations similar to those described by Kammerer are preserved in the Biologischen Versuchsanstalt in Vienna, as a material result of Dr. Kammerer's studies. Both sets of preparations agree fully with the description given by Kammerer. The controls figured by Kammerer, as well as those in Vienna and New York, exhibit a smooth epidermis, while that labelled as coming from the modified individual is thrown into numerous cornified and pigmented spines. It has been claimed that these spines are distinctive in form, and hence the pads must have been produced experimentally in Alytes.

Now, it is a well-known fact that the nuptial spines (and also the pad glands) vary enormously in size within a species. Champy (1924, " Les Caractères Sexuels," Paris, Fig. 104) has well shown how these may vary within the species *Rana temporaria*. My sections of the nuptial pads of *Bombinator igneus* differ enormously from those figured by Lataste of the same species (Kammerer, 1924, *op. cit.*, Fig. 11, sketch 8), for my animal was a terrarium animal in not very good health before it was killed. However, I have attempted in a series of forms to discover breeding pads which agreed in histological detail with the sections sent Dr. Uhlenhuth. My sections of *Bombinator maxima* agree most closely with Kammerer's sections. There is no difference in the height of the spines, their distance from each other, their form, the character of the cores within the spines, etc., between some parts of the pad in this species and parts of the sections sent Dr. Uhlenhuth. But the spines differ in proximity and height in different parts of the pads, which only goes to show that the exact form of these spines is of no value in distinguishing many species of frogs. Kammerer's sections fall within the range of variability shown by the genus Bombinator (more properly called Bombina).

The second group of evidence is to be derived from the photographs. I fail to find anything distinctive in the photograph of the specimen made in Vienna (Kammerer, 1919, *op. cit.*, Pl. x.) or that taken in Cambridge (Kammerer, 1924, *op. cit.*, Fig. 9). Dr. Przibram believes that still a third photograph, one made in Vienna (see the following note) proves conclusively that asperities were present. This photograph is not available to me, but I do not understand how asperities so small as those in Kammerer's sections would show up as Dr. Przibram points out. What proof have we that these " two or three spines " are not foreign bodies; and why do they not show up in the rather good photograph made in Cambridge (Kammerer, 1924, *op. cit.*, Fig. 9) ?

In marshalling the third group of evidence, Dr. Przibram has brought together some distinguished names. With all deference to these gentlemen, I would say that the epidermis of Kammerer's specimen which is underlaid by the black substance appears, in part, slightly irregular. This appearance is probably due to the unequal distribution of the black substance below. At least, it required on my part the most careful manipulation of the lighting to prove that these irregularities were not in the epidermis. Further, I fail to see how any one qualified to pronounce on the presence or absence of nuptial pads could have examined the black discolorations on the forelimbs of Kammerer's specimen without noticing their artificial character.

A final objection which might be raised to the conclusions reached above is that some evidence has been recently presented (Kändler, 1925, *Jen. Zeitschr. f. Naturw.*, **60**, pp. 175-240, Pls. 9-10) to show that the male Alytes may sometimes produce an incipient breeding pad. It is not my purpose to discuss whether the slight crenulations in the surface of the epidermis can be interpreted as an incipient pad. The breeding asperities Kammerer claims to have produced are true nuptial spines similar to those of Bombinator and cannot be compared with the epidermal irregularities of the prepollex or surrounding regions in an occasional male.

The only specimen resulting from the experiments of Kammerer has been the source of much heated argument in NATURE. By describing accurately, for the first time, the modifications in this specimen, we have proved conclusively that no pads are present. Whether or not the specimen ever possessed them is a matter for conjecture.

(2) By Dr. HANS PRZIBRAM, Biologischen Versuchsanstalt, Vienna.

It is clear from the foregoing account that the only one of Kammerer's experimentally modified Alytes still preserved cannot in its present state be regarded as a valid proof of the nuptial pads artificially produced in this species. We must endeavour to decide if the state the specimen is in now agrees with the state at the time of its preservation and before. The specimen is poorly fixed and preserved. Moreover, the epidermis is at several places ready to be shed or even shedding. It is a known fact, as Prof. Franz Werner, of Vienna, asserts, that during repeated handling and shaking the nuptial asperities get lost easily. The specimen has made the voyage to England and back again, and it does not look the better for it. Fortunately, there are photographic plates in existence showing the state of the specimen before it left Vienna for Cambridge and during its stay in England. One of these photographs was taken in the presence of Dr. J. H. Quastel in the atelier of Reiffenstein (Vienna), and the negative travelled with Dr. Quastel to England and has been in the possession of Mr. M. Perkins (Trinity College, Cambridge) since April 1923. A reprint of it is given in Kammerer's " Neuvererbung," Stuttgart-Heilbronn, W. Seifert-Verlag, 1925 (Abb. 9, facing p. 20).

Dr. Quastel asserts in a letter to me, dated Trinity College, Cambridge, March 27, 1926, " with confidence that in the large negative of Alytes (taken by Reiffenstein) there are no traces of any manipulation or retouching of the actual image of the Alytes." Since he is not an expert in photographic matters, he has had the negative examined by an expert photographer, Mr. W. Farren, who gives the following statement : " 76 Regent Street, Cambridge, March 26, 1926.—I have examined carefully the negative of Alytes, and while it appears to have been intensified and a string across the background retouched, there are no signs of any retouching or interference with the image of the specimen itself, or of that part of the background with which it is in contact " Mr. Perkins writes (March 20, 1926) : " The only retouching which the plate has ever shown is a certain obliteration of the thread which supports the specimen, and the fact that retouching has been applied to this, in order to make it uniform with the background, enables one to state positively (from comparison) that neither the image of the specimen itself nor any point of its outline has ever been interfered with by retouching or any other process ; more particularly does this apply to the external (concave) margin of the palm, where two or three spines are obviously and clearly visible. In April 1923 I had many opportunities of examining the specimen, and was always able to see the spines, whether by means of a lens or a dissecting microscope, exactly as in the photograph in question." Dr. Quastel also testifies that the copy represents the state of the specimen when it was photographed in Vienna. There seems, therefore, to be no doubt of the genuineness of the negative and photograph. Moreover, many other zoologists had examined the specimen during its stay in England, some of whom Prof. MacBride gives a list of in a recent letter to me (dated February 26, 1926, Imperial College of Science, South Kensington, London) : E. Boulenger, H. M. Vevers, Cannon, F. S. Harmer, J. Stanley Gardiner, Borradaile, and F. Potts.

Further proofs that the Alytes in question has borne nuptial callosities in the epidermis may be found in the microscope sections of the skin that had been removed from the same specimen during the height

of the breeding season from the other (right) hand. The comparison both of Kammerer's pictures in his original paper (*A. f. Entwickl. mech.*, 45, 323, 1919, Pls. x., xi.) or in his "Inheritance of Acquired Characteristics," Boni and Liveright, New York, 1924 (Figs. 10-11, facing p. 62) and of the section photographed in America with nuptial pads of other Anura, show clearly that the callosities differ from all other known pads, resembling most those of other Discoglossidæ, as Bombinator, but still *Discoglossus pictus* (after Lataste; see Kammerer, 1924, Fig. 11 N. 3). This had already been pointed out by Mr. Perkins (NATURE, August 18, 1923, p. 238). Lastly, it may be mentioned that quite recently the possibility of Alytes developing nuptial pads has been shown in a specimen found in Nature and examined by R. Kändler (*Jenaische Z.*, 60, 175, 1924, Pl. 10, Fig. 12). Although it is only just a beginning of callosities in one male taken in Westfalen (Germany), when compared with the usual smooth surface of the Alytes hand it becomes significant. Kändler found the callosities in this one male on the palmar and dorsal side of the thumb, on the inner side of the third and fourth finger. The callosities resemble those which Kammerer figured for the F_2 generation of water-bred Alytes (*l.c.* Pl. xi. Fig. 4). There were no typical nuptial pad-glands Kändler also questions if those described by Kammerer were of this character, as Kändler's females showed the same type of gland with granular content too. But no females showed callosities. Kändler has also figured the nuptial pad of other Anura, *i e. Bombinator igneus* (Pl. 10, Figs. 8A, 9). This figure is in accordance with that of Lataste.

Whilst it is possible to come to a probable solution with respect to the spiculæ, we have not been able to elucidate the origin of the black substance. It is clear that it has nothing to do with the black pigment often seen in nuptial pads of Anura other than Alytes, or with the patches described and in the progeny of non-egg carrying Alytes males by Kammerer, 1909. The only possibility we can think of is that some one has tried to preserve the aspect of such black nuptial pads in fear of their vanishing by the destruction of the melanin through exposure to the sun in the museum case, by injecting the specimen with India ink. Kammerer himself was greatly astonished at the result of the chemical tests, and it ought to be stated that he had been asked and had given his consent to the chemical investigations. He would suggest that somebody had made such injections to get him into difficulties were it not that he remembers the black substance to have been in the same place and amount even in the living animal (letter to Przibram, February 18, 1926). So the case remains obscure.

We may conclude as a result of these observations:

(1) The only one of Kammerer's specimens of Alytes still preserved is not valid as a proof of the nuptial pads, at least not in its present state of preservation.

(2) No asperities are to be seen now, but by photographs taken before the specimen was sent to England it must be inferred that the spiculæ have been lost through the shaking of the voyage and repeated handling.

(3) Photomicrographs of the sections said to have been prepared from the skin of the same specimen some time before its preservation in the height of the breeding season show in several points different characters from nuptial pads of other Anura, even of Bombinator, coinciding more closely with those of Discoglossus (next relative to Alytes), and the picture of a rudimentary nuptial pad found on a male Alytes in Nature by Kändler (1924).

(4) The black substance in the whole specimen has nothing to do with melanin and is not restricted to a nuptial pad region.

(5) With this conflicting evidence it is greatly to be desired that the experiments of Kammerer on Alytes may be taken up again by some one of equal skill in rearing Anura

The Progress of Geological Survey in Great Britain.

THE area described in the first [1] of the Memoirs of the Geological Survey of Great Britain referred to below lies in Ross-shire and Sutherland The north-western corner is occupied by Lewisian, Torridonian and Cambrian rocks, all of which have been involved in the great Caledonian thrusts of the N.W. Highlands. Of special interest are the alkaline igneous rocks of Loch Ailsh. They form a composite laccolith of post-Cambrian and pre-thrusting age, made up of types ranging from perthosite (a new type composed principally of perthite) to pyroxenite, and resembling in many ways the well-known Oslo suite of rocks made classic by Brögger. Convincing evidence is adduced to show that the alkaline character is original, and quite independent of the intimate association of the intrusion with the Cambrian dolomites. Another feature of petrological importance is the description of the newer igneous rocks, which here present clear evidence of permeation and hybridisation.

The area dealt with in the second memoir [2] in our list, Golspie, lies to the east of the preceding, and includes the coast of Sutherland from Dornoch to Helmsdale. The earlier chapters are devoted to the physical features, and to the schists and gneisses belonging to the Moine series and the older and newer igneous rocks associated with them. The marginal complex of injected and other metamorphic rocks around the Rogart granite is fully described, and hybrids like those alluded to above also occur. The Old Red Sandstone covers considerable areas in the sheet, and along a narrow coastal strip Mesozoic rocks are present, ranging from the trias to the Kimeridgian. The final chapter gives an account of glacial phenomena, peat deposits, and raised beaches.

Iona and Staffa are visited every summer by an increasingly large number of tourists, and those who are interested in geology will appreciate the publication of a Memoir referring to this region.[3] Those who are not will become interested despite themselves, for the islands abound in geological features which are part of their attraction. The famous Ardtun Leaf Beds and Macculloch's Tree are fully described; and the columnar basalts of Fingal's Cave and other parts of Staffa are discussed on the lines followed in the recent Memoirs on the Isle of Mull.

The account of the geology of the extreme north of England given in the Memoir on Berwick and the neighbouring country [4] is welcome as a sign that the

[1] The Geology of Strath Oykell and Lower Loch Shin. (Explanation of Sheet 102 of the Geological Map of Scotland.) By Dr. H. H. Read, J. Phemister and G. Ross, with contributions by C. H. Dinham and M. Macgregor. Pp. vi+220+2 plates. 6s. net.

[2] The Geology of the Country around Golspie, Sutherlandshire. (Explanation of Sheet 103 of the Geological Map of Scotland), including a description of the Mesozoic Rocks of East Sutherland and Ross. By Dr. G. W. Lee, Dr. H. H. Read, G. Ross and J. Phemister. Pp. vi+143+1 plate. 3s. 6d. net.

[3] The Geology of Staffa, Iona, and Western Mull. (A Description of Sheet 43 of the Geological Map.) By E. B. Bailey and E. M. Anderson, with contributions by G. A. Burnett, J. E. Richey, Dr. G. W. Lee, W. B. Wright and G. V. Wilson, and Petrological Notes by Dr. H. H. Thomas. Pp. iv+107+1 plate. 3s. net.

re-survey of Northumberland is now well under way. The chief points of interest are the descriptions of the Scremerston coalfield and the very striking coast sections to the north of the Tweed. Memoirs on the sheets to the south are due for early publication, and should be of importance in so far that they will contain references to the northern boundary of the Whin Sill. It is in itself significant that this Memoir, the first of the promised series, contains no mention of any igneous rocks.

The greater part of the Pottery coalfield of North Staffordshire is included in the sheet described in the Memoir on Stoke-upon-Trent.[5] An account of the coal measures with their important coal seams and iron ores naturally takes first place. There is also a valuable chapter on faults and folds; and as a feature appearing for the first time in this edition, descriptions of the post-Triasic Bullerton dyke and of the other intrusions of the area are given. It is interesting to notice that Dr. Scott, who has studied the Tertiary and Carboniferous alkaline rocks of Scotland, directs attention to the petrological affinities of the former with the intrusive rocks of North Staffordshire. He thinks that the Rowley Regis and Clee Hill rocks are likely to be also of Tertiary age.

Passing now to Epping Forest and the eastern suburbs of London,[6] we find only Eocene, Pleistocene and later deposits. The Chalk, however, underlies the whole area, and the question of deep-seated water supplies is discussed, and illustrated by a contour map of the sub-Tertiary Chalk surface. On the south the subsoil consists mainly of the deposits made by the Thames; the central part is chiefly London clay; while to the north the region is diversified with hills capped with Bagshot sand and glacial deposits. These beds are discussed with special reference to sanitation and agriculture.

Air Pollution and its Prevention.

THE citizens of Leeds, under the auspices of the Mayor and City Council, have instituted a campaign against smoke to commemorate in a practical form the tercentenary of the granting of the statute to the city. In connexion with this effort, a pamphlet entitled "Clean Air for Leeds" has been prepared by a Committee, of which Prof. J. B. Cohen is chairman, formed on the invitation of the Lord Mayor to consider the question of "a cleaner city on the lines of smoke abatement." The pamphlet has been prepared for free distribution, and aims at informing the public as to the present condition of the smoke problem.

Leeds is to be congratulated on facing her own smoke problem in this way. A visitor, unless from another Midland city, cannot help being struck by the prevailing sooty blackness of the buildings. It is surely a merciful provision of Nature that people adjust themselves so easily to environment; had this not been so, life in some of our smoke-blackened cities must appear scarcely worth living. It is, however, this adjustment to environment which blinds our eyes more or less to the true condition of affairs. Leeds has a useful field for effort here. The pamphlet gives a short analysis of the problem of smoke abatement and the remedies available. The sources of air pollution, cause, nature, and effects of smoke are all dealt with briefly.

The general conclusions of the Departmental Committee on Smoke Abatement are quoted, and it is clear enough that this committee had no hope of a solution of the problem by the initiative of local authorities unless subject to the stimulus of Government. The new Bill now before Parliament must provide the necessary stimulus or it will not go very far towards a solution.

The Leeds pamphlet should be of great use in keeping the problem before the public mind. Reference is made on page 24 to the standard gauge used by the Advisory Committee on Atmospheric Pollution, and the Leeds committee criticises this gauge on the grounds that "the amount of solid matter is largely dependent on the situation with regard to the wind and the nature of the ground on which the gauge rests." The Committee then proceeds to recommend a method devised by Prof. Cohen many years ago, involving the exposure, in different localities, of glass plates, upon which some of the deposited matter adheres. These plates are afterwards washed in running water under a tap, and the deposit estimated by its opacity, or other means. The Advisory Committee, we believe, had this method before it when considering the most suitable means for measuring deposited impurity, and the method was discarded as not fulfilling the necessary conditions. While the exposed plate method has all the drawbacks attributed by the Leeds committee to the standard deposit gauge, it has also others of its own, which influenced the Advisory Committee in deciding to adopt the gauge method. The plates cannot be any more independent of position or wind than the gauges, while the deposit retained by the plates is not the total but some unknown and variable fraction of it, depending on the stickiness of the deposit, whether the plates are wet or dry, the weather, and so on. It may also be supposed that a plate which has received a first deposit of tarry soot will be more effective as a trap than one which starts with a less sticky layer of ash or grit. The only sound procedure is to catch in some way the whole of the deposit—hence the Advisory Committee's standardised gauge.

It is to be hoped that Leeds will not depart from this method of measuring deposit, as a great part of the value of the results lies in their being comparable with those from other cities.

The open coal fire is discussed in the pamphlet, and the conclusion is given that raw coal cannot be burnt in an open grate without the production of smoke. The use of smokeless sources of heat is recommended, of which gas, coke, and electricity are specifically mentioned and discussed. The advantages of the gas fire, its cleanliness and cheapness, are referred to, while the use of coke in domestic fires is advocated; but, as the pamphlet goes on to say, "it is not every kind of fireplace nor every kind of coke which is suitable for burning in an open fire." The relative costs of heating by coke, coal, gas, and electricity are discussed; the figures arrived at indicate coke to be much the most economical source of heat.

A section at the end deals with the law relating to the smoke nuisance, and the new Government Bill is discussed. The committee, in its final recommendations, lays great stress upon the need to educate the public in the use of smokeless methods, and, on the whole, it is to be congratulated on its public-spirited efforts to clean the air of Leeds.

University and Educational Intelligence.

Cambridge.—The trustees of the Busk Studentship in Aeronautics, founded in memory of Edward Teshmaker Busk, who lost his life in 1914 whilst flying an experimental aeroplane, have awarded he studentship for the year 1926–7 to Mr. P. B. Walker, of Peterhouse.

London.—The Rogers Prize of 100*l.* for 1926 has been awarded to Dr. Robert Coope for an essay entitled "The Value of the Various Methods of Investigating Diseases of the Pancreas."

The University Studentship in Physiology for 1926–1927, of the value of 50*l.* and tenable for one year in a physiological laboratory of the University or of a school of the University, has been awarded to Mr. E. T. Conybeare, who proposes to undertake research in physiology at Guy's Hospital, particularly on the clinical side, and possibly also to extend his work on anæthesia in relation to its clinical application.

The University College Committee will shortly appoint either a full-time assistant or two part-time assistants in the Department of History and Method of Science. Candidates must be graduates either in biology, or in physics, or in astronomy. A good working knowledge of at least two foreign languages is desired.

Miss Helen Masters has been appointed Head of the Domestic Science Department and the Training College for Teachers of Domestic Science of the Battersea Polytechnic, London, S.W.11, in succession to Miss Marsden, who is retiring after nearly twenty-seven years' service. Miss Masters holds the King's College Post Graduate Diploma in Household and Social Science, and has been, for the past fifteen years, on the staff of the Household and Social Science Department of King's College and has acted as examiner in domestic science for the University of London.

The secretary of the Council on Medical Education and Hospitals of the American Medical Association has contributed to *School Life* for April an article on "Rural Schools as Centres of Medical Service and Community Life." The position of the country doctor in the United States has for many years been becoming more and more precarious owing to an increasing tendency on the part of residents in country districts to resort to town practitioners. Meanwhile the rural school consolidation movement has been proceeding apace. The consolidated and improved rural school has definitely proved its worth and gone far beyond the experimental stage. The plan, which is being rapidly adopted throughout the States, involves the transportation of pupils from all parts of a large district to and from the consolidated school in motor omnibuses, and this makes it necessary also that the roads leading to the school from all directions should be kept in fair condition. "Why," asks Dr. N. P. Colwell, the writer of the article, "should not the locations of these schools become rural community centres for other than educational purposes?" A health centre or clinic either in the school or in a separate building could serve not only the children attending the school but also other people living in the district, and the motor omnibus service could doubtless be induced to co-operate. Such a scheme, either by itself or in conjunction with a guarantee by a number of influential residents, would, it is suggested, suffice to secure for the district the services of a competent physician.

Contemporary Birthdays.

August 10, 1865. Sir Charles Frederick Close, K.B.E., F.R.S.
August 10, 1862. Prof. William Joseph Hussey.
August 11, 1852. Prof. Harold Baily Dixon, C.B.E., F.R.S.
August 12, 1860. Sir Sidney Gerald Burrard, K.C.S.I., F.R.S.
August 13, 1861. Prof. Herbert Hall Turner, F.R.S.
August 13, 1879. Dr. Philip Gosse.

Sir Charles Close, formerly an officer in the Royal Engineers, was Director-General of the Ordnance Survey from 1911 until 1922. He is an active general secretary of the International Geographical Union.

Prof. Hussey, director of the Detroit Observatory of the University of Michigan, was born at Mendon, Ohio. From 1911 until 1917 he was director of the Observatorio Nacional de La Plata, Argentina. He has done excellent work in choice of sites for observatories in Southern California, Arizona, and Australia, working for the committee on observatories of the Carnegie Institution. Prof. Hussey was awarded the Lalande prize of the Paris Academy of Sciences in 1906 for double star discoveries and investigations. He is a foreign associate of the Royal Astronomical Society.

Prof. H. B. Dixon was educated at Westminster School and Christ Church, Oxford. His life's work was carried out at Manchester as occupant of the chair of chemistry in the University there, in succession to Sir Henry Roscoe. The Royal Society awarded Prof. Dixon a Royal medal in 1913, on the ground of his eminence in physical chemistry, especially in connexion with explosions in gases. He was president of the Chemical Society, 1909–11. Prof. Dixon, it may be recalled, was president of the chemical section at the last meeting of the British Association held in Oxford, namely, that in 1894. He gave an address on "An Oxford School of Chemists."

Sir Sidney Burrard was Surveyor-General of India from 1910 until 1919; formerly he held office as Superintendent of the Trigonometrical Survey of India at Dehra Dun. Whilst in charge he was responsible for the success of the most extensive system of geodetic triangulation ever inaugurated. His works on the geography and geology of the Himalayas and Tibet (in conjunction with the late Sir Henry Hayden); on the effect of the Himalayas on the plumb-line in India; and on isotasy, have given him special repute as a scientific investigator.

Prof. Turner was born at Leeds, and was educated at Clifton College, and also at Trinity College, Cambridge. Formerly chief assistant at the Royal Observatory, Greenwich, he was next appointed Savilian professor of astronomy in the University of Oxford. He has done yeoman service for the British Association, having been one of the general secretaries from 1913 until 1922. He was president of the Royal Astronomical Society, 1903–5. Prof. Turner is Hon. D.Sc. Leeds and Sydney, and a corresponding member of the Paris Academy of Sciences.

Dr. Gosse is the grandson of that engaging personality, Philip H. Gosse, F.R.S., who died in 1888, author of works on marine zoology, and on the microscope. Educated at Haileybury and St. Bartholomew's Hospital, Dr. Gosse is assistant superintendent of the Radium Institute. He acted as naturalist to the FitzGerald expedition to the Andes (1896).

Societies and Academies.

PARIS.

Academy of Sciences, June 28.—A. **Lacroix**: The fused veins of meteorites and their analogy with the 'pseudotachylites' of distorted terrestrial regions.—Charles **Moureu**, Charles **Dufraisse**, and Paul Marshall **Dean**: A dissociable organic peroxide: rubrene peroxide. The hydrocarbon rubrene described in an earlier communication, when exposed to sunlight in benzene solution, rapidly absorbs oxygen, thereby losing both colour and fluorescence. From the solution a white crystallised product containing solvent of constitution is obtained, which dissociates on heating into solvent, rubrene and oxygen. It is pointed out that the existence and dissociation of this peroxide is of great theoretical interest.—Léon **Guillet**: The cementation of steels by silicon. The object of these researches was to obtain a film of high silicon steel on a mass of mild steel retaining the mechanical properties of the mild steel with a chemically resistant skin. In all of the experiments cited the cemented skin was too fragile.—**Neymann**: The laws of probability which tend towards the law of Gauss, remaining infinite in the neighbourhood of a point.—Jules **Drach**: The integration of the equations $r+f(s, t)=0$.—Silvio **Minetti**: The radius of convergence and the singularities of a class of analytical functions defined by Taylor's development.—R. **Gosse**: A special class of equations of the form $s=f(x, y, z, p, q)$.—G. **Alexitch**: Conjugated trigonometrical series.—André **Charrueau**: Some geometrical properties of surfaces of equilibrium relative to a liquid mass of revolution, in uniform rotation round its axis of revolution.—J. **Villey**: A simple model of electrometer of low capacity.—H. **Pelabon**: Detection (of electromagnetic waves) by metallic contacts. A symmetrical detector. A stable detector can be made from two steel balls of the same diameter (3 cm.) suspended from an insulating support by copper wires 15 cm. long. The effect appears to be independent of the nature of the interposed dielectric.—**Volmar**: The photolysis of the alcohols. The photochemical decomposition of the alcohols under the influence of the radiation of the quartz mercury vapour lamp takes place in two stages, the dehydrogenation of the alcohol giving aldehyde and ketone and the photolysis of the latter.—Henri **Belliot**: Experiments on photographic inversion.—Victor **Henri** and Sv. A. **Schou**: The ultra-violet absorption spectrum of the vapour of formaldehyde. New type of spectrum of Y-shaped molecules. The movements of rotation of an asymmetric molecule possessing three unequal moments of inertia cannot be resolved mathematically, but when two of the moments are equal an expression for the energy of the molecule can be found (Sommerfeld, Born, Reiche). The vapour of formaldehyde is composed of such molecules, and a study of the absorption spectrum shows that its structure corresponds very exactly with the formulæ for symmetric molecules having two different moments of inertia. Other substances which may be expected to show similar spectra are phosgene, thiophosgene, acetone.—**Consigny**: The influence of metallic screens on the form of the ionisation curves of the α-rays.—R. **Mellet** and M. A. **Bischoff**: Chemical reactions and volumetric titrations in Wood's light. The fluorescence of the solution is used as the indicator; possible uses of the method are given.—M. **Bourgeaud**: The electrometric study of the allotropic forms of mercuric sulphide.—P. **Job**: Some applications of the spectrographic method to the study of complexes in solution. The substances examined were a solution of iodine and potassium iodide in alcohol, potassium mercurichloride in aqueous solution, and the double bromide of cadmium and potassium. In the first of these the iodide of potassium behaved as though present in triple molecules, giving the complex $(KI)_3$.—J. **Errera**: The polarisation of a medium and its molecular structure. The electrical moments of the dihalogen derivatives of benzene.—Edmond **Vellinger**: The rotatory power of organic bodies as a function of the *p*H: glucosamine. A curve is given showing the rotatory power of glucosamine as a function of the *p*H. It resembles the curve obtained by Mlle. Liquier for asparagine. A formula is developed from theoretical considerations which corresponds closely with the experimental results.—A. **Travers** and **Houot**: The tempering of type-metal alloys. The dilatometric study of monotype and stereotype alloys shows clearly, after three months, the influence on these alloys of time elapsed after tempering. The contraction appears to be mainly due to the proportion of tin.—G. **Flusin** and H **Giran**: The estimation of calcium carbide in calcium cyanamide. The acetylene produced by the action of water on the calcium carbide present is passed into ammoniacal silver nitrate solution, the mixed precipitate of silver acetylide and sulphide treated with hydrochloric acid, the chloride dissolved in ammonia, and the solution titrated with standard potassium cyanide.—A. **Kirrmann**: Magnesium reactions starting with 1:3 dibrompropylene. The reaction of this dibrompropylene with methyl magnesium bromide is very complex, and the following products have been isolated: ethane, erythrene, bromobutene, octadiene, and a hydrocarbon which is probably $C_{10}H_{18}$.—Paul **Baud**: The pulp of the agave as a source of industrial alcohol.—P **Idrac**: Records of the electrical field of the atmosphere up to a height of 20,000 metres. Results of experiments made at the Trappes Aerodynamical Observatory with captive balloons There are some irregularities, but on the average the electrical field decreases up to 9000 metres. The mean result gives a field of 10·4 volts per metre at 4000 metres, 5·6 volts at 6000 metres, and 2·3 volts at 8000 metres. At higher altitudes the values are much higher, being 30 or 40 volts per metre in the neighbourhood of the isothermal layer (10,000 to 12,000 metres).—Georges **Corroy**: The Spiroferideæ of the European Lias.—H. **Colin** and A. **de Cugnac**: The various types of the grass family according to the nature of their reserves of hydrocarbons.—S. **Metalnikow** and V. **Chorine**: Conditional reflexes in immunity.—A. **Alivisatos** and Fernand **Mercier**: The action of crystallised violet on the cardio-vascular apparatus of the dog. Crystallised violet (hexamethylpararosaniline chloride) appears to act on the heart in a manner resembling the digitalis alkaloids. It exerts a stimulating action on the pneumogastric nerve, to which is added a specific action on the myocardium, producing an augmentation of the tonus and energy of the heart.—J. J. **Thomasset**: The presence of cells in the dentine of some elasmobranchs.—Paul **Chabanaud**: The frequency, symmetry and specific constancy of external hyperostoses in various fishes of the family of Sciænoides.—P **Portier**: The genesis of the secondary nucleus of natural pearls.—Mme. Anna **Drzewina** and Georges **Bohn**: The action of metallic silver on the sperm and larvæ of the sea urchin. A discussion of the sterilising action of silver vessels.—H. **Barthélemy**: Biometrical and experimental researches on the hibernation, maturation, and supermaturation of *Rana fusca*.—A. **Vandel**: The relations between sexual reproduction and parthenogenesis in the terrestrial Isopod *Trichoniscus* (*Spiloniscus*) *provisorius*.

CAPE TOWN.

Royal Society of South Africa, May 19.—E. L. **Gill**: An early embryo of the blue whale. The embryo was taken from a blue whale (*Balænoptera sibbaldi*) at Saldanha Bay and is at the stage reached by the human embryo at about the twenty-eighth day. Though still in the main a generalised vertebrate embryo, it shows hints of cetacean characters in the small eye, large jaw elements, short neck and reduced branchial arches, large genital papilla, and close segmentation. The fore-limb bud is large, but there is no visible trace of a hind limb. In size (about 6·5 mm.) it agrees closely with other embryos of the higher vertebrates (*e.g.* chick, rabbit, man) at the same stage of development.—C. von **Bonde** and D. B. **Swart**: The structure of the plathander (*Zenopus lævis*) (Pt. i.). The animal presents many primitive features, being related ecologically with the Dipnoi and morphologically with the Anuran and Urodelan amphibia. Notable points with regard to the external features are (*a*) the abundance and properties of the secretion of the slime glands; (*b*) the presence of definite groups of dermal sense organs; (*c*) the presence of an eye tentacle in the adult; (*d*) the cloacal lips in the female.—L. **Mirvish** and L. P. **Bosman**: Note on the calcium content of blood. The effect of the injection of extracts of various body tissues, including ovarian and luteal extracts, upon the calcium content of blood has been examined.

SYDNEY.

Linnean Society of New South Wales, April 28.—J. **McLuckie** and A. H. K. **Petrie**: An ecological study of the flora of Mount Wilson. (Part iii.) The vegetation of the valleys. The plant communities represented are the Ceratopetalum-Doryphora association, the *Eucalyptus goniocalyx-E. Blaxlandi* association, the *Eucalyptus piperita* consociation, and the *E. hæmastoma* var. *micrantha* consociation.—C. **Barnard**: Preliminary note on branch fall in the Coniferales. The development of foliar shoots and the associated shedding of branches can be correlated with the phylogeny of the tribes of the conifers. The presence of distinct dimorphism in the branches of conifers seems to be a primitive feature, gradually lost in higher types.—H. J. **Carter**: Revision of the Australasian species of Anilara (Buprestidæ) and Helmis (Dryopidæ), with notes, and descriptions of other Australian Coleoptera.

VIENNA.

Academy of Sciences, June 10.—R. **Weiss**, A. **Spitzer** and J. **Melzer**: On tri-phenyl-methanes, the benzol nuclei of which are bound to each other (ii.) Trimethylene - triphenylmethane - triketondicarbon-acids.—O. **Wettstein**: A new race of mice in Austria, *Evotomys glareolus ruttneri*.—O. **Koller**: Two new forms of fish from the Island of Hainau, a species of Cyprinid and a subspecies.—J. **Schorn**: History and results of seismology in Northern Tyrol.—A. **Defant**: Primary and secondary, free and forced, pressure waves in the atmosphere.—A. **Schedler**: Air pressure waves and correlations over the North Atlantic Ocean.—A. **Roschkott**: Studies on oscillations of air pressure in the region of the Azores highlands.—F. M. **Exner**: Relations of air-pressure anomalies on the earth to each other.—R. **Rotter**: On condensations of unsaturated compounds with diazo-methane.—F. **Knoll**. The differential geometry of the spacial vector field.

WASHINGTON, D.C.

National Academy of Sciences (Proc. vol. 12, No. 6, June).—William **Hovgaard**: Bending of a curved tube of circular cross section. A formula is developed which when applied to pipe bends gives results in good accord with experiment.—E. O. **Salant**: The heat capacity of solid aliphatic crystals (ii.).—R. J. **Havighurst**: (1) The effect of crystal size upon the intensity of X-ray reflection. With a crystal having a linear dimension greater than 10^{-5} cm., intensity is modified by 'extinction,' which may be primary (due to each little block acting as a perfect crystal) and secondary (due to shielding of the inner blocks by those near the surface). Work on powdered sodium chloride, calcium fluoride and calcite indicates that primary extinction is absent in crystals grown from solution and less than 10^{-3} cm. in thickness, so intensity measurements can be used to determine electron distributions. Single crystal measurements of the alkali halides require correction for secondary extinction. (2) The intensity of reflection of X-rays by lithium, sodium and calcium fluorides. Measurements of intensity enable the relative value to be calculated of a factor, the "atomic structure factor," which at small angles of reflection approaches the number of electrons in the atom. This factor is plotted against sin θ (where θ is the angle of reflection) and, finally, atomic scattering curves are drawn; those for fluorine from the different salts are nearly alike, suggesting a force field of constant magnitude, while those for sodium from the chloride and fluoride differ considerably. The total number of electrons gives only a rough idea of the order of the atoms as regards scattering power.—J. H. Van **Vleck**: Note on the postulates of the matrix quantum dynamics. The Hamiltonian equations, the commutability relations, the Bohr frequency condition and the conservation of energy equation can be taken as the fundamental postulates. The Ritz combination principle and the quantum conditions become not merely *sufficient* but also *necessary* for the last two postulates.—Joseph Miller **Thomas**: Conformal invariants. A complete set of integrability conditions which express the laws of transformation of a set of conformal invariants are obtained.—Helen **Barton**: Generalisation of Kronecker's relation among the minors of a symmetric determinant. Kronecker's relation is a special case of a more general relation.—Oliver D. **Kellogg**: On the classical Dirichlet problem for general domains.—Ernest W. **Brown**: The evidence for changes in the rate of rotation of the earth and their geophysical consequences (*v.* NATURE, July 31, p. 170).—Christine **Ladd-Franklin**: The reddish blue arcs and the reddish blue glow of the retina: seeing your own nerve currents through bioluminescence. A band of bright red light thrown on a screen in a dark room appears to have slightly reddish-blue arcs projecting from it on both sides. What is seen, as an entopic phenomenon, is certain fibres of the optic nerve on the surface of the retina. These fibres, when stimulated, seem to give off an 'emanation' which causes fluorescence in the retina.—Thorne M. **Carpenter**: The metabolic effect of enemata of alcohol, dextrose and levulose in humans. Ethyl alcohol is rapidly and nearly completely absorbed; it promotes the elimination of water without removing other constituents of the tissues, increases pulse rate and lowers the respiratory quotient, indicating that alcohol is utilised in the tissues. Dextrose and levulose are not absorbed so rapidly or completely, the respiratory quotient increases with the former, indicating increased utilisation of carbohydrate. Levulose caused the greatest decrease in nitrogen elimination. It is suggested that, administered by rectal injection, these substances are metabolised throughout the body in a manner similar to that in which material is utilised in muscular work.

Diary of Societies.

AUGUST 6 TO 11.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (at Oxford).

Friday, August 6.—At 10 A.M.—Addresses by Sectional Presidents. G.—Sir John Snell: The Present and Future Development of Electricity Supply. L.—Sir Thomas Holland. Discussion (Section C): Problems of the Thames Gravels.—Discussion (Section M): Agricultural Education.

At 11 A.M.—Discussion (Section L): Scholarships

At 11.30 A.M.—Addresses by Sectional Presidents: D. Prof. J Graham Kerr: Biology and the Training of the Citizen.—J.—Dr. J. Drever: Psychological Aspects of our Penal System.—Discussion (Section K): Sex Determination in Plants.

At 2.30.—Discussion (Section I): The Relationship of Vitamin B to Bios.—Discussion (Section L). The Cinema in Education.

At 3.15.—Discussion (Section I): The Meaning of the Symptoms of Beri-beri.

At 3.30.—Discussion (Section L): Wireless in Education.

At 8.—Prof. A. S. Eddington. Stars and Atoms (Evening Discourse).

Monday, August 9.—At 10 A.M.—Addresses by Sectional Presidents: A.—Prof. A Fowler. The Analysis of Spectra.—H.—Prof. H. J Fleure: The Regional Balance of Racial Evolution.—M.—Sir Daniel Hall: The Limits of Agricultural Expansion.—Discussion (Section B): Tautomerism.—Discussion (Section L): Recent Advances in Educational Science.

At 11 A.M.—Discussion (Section K): Vegetative Propagation.—Discussion (Section D): The Training of a Zoologist.

At 2.—Discussion (Sections D, H, J): Heredity in its Physical and Mental Aspects.

At 8.—Prof. H F. Osborn: Discoveries in the Gobi Desert by the American Museum Expeditions (Evening Discourse).

Tuesday, August 10.—At 10 A.M. Prof. J. S. Huxley: The Study of Growth and its Bearings upon Morphology (Lecture).—Discussion (Section L). The Public School System.

At 11 A.M. Discussion (Sections C, D, K): The Conception of a Species.

At 11.30 A.M. Discussion (Section M): The Feeding of the Dairy Cow.

At 12 noon.—(Section I) by Dr. J. S. Haldane: Acclimatisation to High Altitudes (Lecture).

At 2.—Conference of Delegates of Corresponding Societies.

At 2.30.—(Section J) by Miss W. Spielman: Recent Progress in Vocational Selection (Lecture).

At 5.—Sir F Keeble: The Nervous System of Plants (Lecture).

Wednesday, August 11.—At 11 A.M.—Discussion (Section E): Regional Work in Geography.

At 12 noon.—Concluding General Meeting.

SATURDAY, AUGUST 14, 1926.

CONTENTS.

Economics of the Coal Industry.

MR. FRANK HODGES recently addressed the Royal Society of Arts upon the all-important subject of the economics of the coal industry, and his very thoughtful and well-reasoned address may be unreservedly recommended to all interested in the matter, that is to say, at this moment to every thinking man throughout Great Britain. The authoritative statistics which Mr. Hodges produces show more clearly than words the basal reasons for our difficulties, and most of them are summed up in the following quotation:

"The Ruhr hours are 8 hours for each man, and those of Upper Silesia, in Poland, are 8½ hours for each man. Wages costs in Great Britain are per ton 12*s.* 3*d.*; in the Ruhr they are 7*s.* 10*d.*; and in Poland 3*s.* 8*d.* The wages of all persons employed in British mines are 10*s.* 5*d.*; in the Ruhr 7*s.* 4½*d.*; in Polish Upper Silesia 3*s.* 6*d.* per shift.

The latest figure of output per shift in Great Britain was 18·4 cwts.; in Germany 21 cwts.; in Upper Silesia 22·06 cwts."

Mr. Hodges points out the inevitable result of these figures, namely, that in the coal export trade "Great Britain has lost both relatively and absolutely in the coal business of the world." It is not so many years ago since a general strike in Great Britain would have produced something like a panic, not only in this country but also throughout industrial Europe, which at one time was practically dependent upon Great Britain for its coal supplies. To-day, Europe cares nothing whether the British coal mines are working or idle; nay, more, the rest of the world is quite capable of supplying British needs. Mr. Hodges points out cogently that this unpleasant fact is due to our high prices and low output per man. He does not deal with the contributory cause, namely, that British coal miners have by repeated strikes taught the rest of the world how to do without British coal. It is because of these strikes that other nations have been forced to develop their own coal resources as well as other sources of power, notably water power, which have replaced British coal. A notable example in point is Switzerland, which has developed its hydro-electric powers and electrified its railways, mainly because, as a Swiss engineer put it, they are determined to have a source of power that *will not go on strike.*

The point cannot be too strongly stressed that a definite proportion of the old-time export coal trade of Britain is gone for ever. The only way to secure some share in what is still left is to bring down British prices of coal production to a competitive basis. Mr. Hodges seems to think that some relief may be obtained by a better use of the coal so as, in his words, to "bind

up production of the raw fuel with the production of electricity and gas and by-products." At best, however, this remedy can only be a palliative; however well the coal is utilised when it is produced, nothing will ever avail to counterbalance the cardinal fact that British coal costs too much to produce. Other nations can use coal as effectively as we can, and if they produce it more cheaply than we do, they will still be ahead of us in world competition. In justice to Mr. Hodges, it must be said that he appears to appreciate this fact, and is clear on the point that the only remedy is lower wages or longer hours of work. He has come to the conclusion that, of the alternatives, "a modification of hours . . . is the least of two evils." His proposed remedy is a 45 or 46 hour week; it is highly probable that many of those who have studied the subject carefully will scarcely be inclined to agree with him that this is going quite far enough, or to hold, as he does, that if the working week is increased to 48 hours, other countries in Europe will increase their hours also. This proposition may well be doubted in view of the fact that wages per hour in Britain are practically twice as high as they are even now in the Ruhr.

There will no doubt be a general consensus in favour of Mr. Hodges' suggestion that there should be a five-years' agreement in order to get the industry back on to a sound basis. He realises quite clearly that reorganisation of the collieries, where such is required, cannot be done without an influx of fresh capital, and that to get such an influx, terms acceptable to the capitalist must of necessity be offered. Mr. Hodges, like every other intelligent man, sees that British coal miners must accept the inevitable, and that it is useless to fight against natural laws and economic facts. Our only hope of salvation lies in producing coals more cheaply; whether the coal miner prefers to attain this end by working longer hours or by accepting lower wages, is a question which he ought to be allowed to decide for himself. One or other alternative, or a compromise involving something of each, is the inevitable solution, and it is for the coal miner to say which he prefers. If neither is accepted, then we must be prepared to contemplate an end to British coal mining.

The Protection of Wild Life in Australia.

Save Australia: a Plea for the Right Use of our Flora and Fauna. By various Writers. Edited by Sir James Barrett. Pp. viii+231. (Melbourne and London: Macmillan and Co., Ltd., 1925.) 8*s.* 6*d.* net.

THE march of civilisation inevitably betokens the retreat of the native plants and animals of a country. For long the retreat passes unnoticed: the early settlers, battling with Nature for a foothold, have little inclination to survey any but the most immediate effects of their handiwork, and it is left for their more leisured successors to develop the æsthetic sense which laments the disappearance of the primeval natives of the land. It is on this account the more gratifying to find that a comparatively new country like Australia, with its unique fauna and flora, has tackled the problem of its disappearing animals and plants with an energy which puts to shame the puny efforts made in the 'old country.'

Four main causes are said to account for the disappearance of Australian animals. Two are inevitable, and are practically beyond the modifying power of man. (1) His settlements and cultivation open up the country at the expense of the shelters, the feeding-places and the breeding-places of many of the wild animals. (2) Epidemic disease may sweep with dire effect through the populations of large areas, as in 1898-99 and 1901-2-3, when koalas, dasyures, certain bandicoots and other forms were almost exterminated in a tract from central Queensland to Victoria. The other two causes are looked upon as equally serious, and they are preventable. (3) The deliberate introduction and setting free of such aliens as the fox, the cat, the rabbit, and many species of European birds has, either by direct destruction or by the consumption of the food supply and occupation of nesting sites, played havoc with many of the natives. Mr. Le Souef alleges that the fox has cleared off practically all the small ground animals outside the coastal districts in eastern and southern Australia, and the immunity of the inhabitants of the coastal districts is due to the presence of the poison tick, *Ixodes holocyclus*, which is fatal to foxes and dogs. (4) Deliberate destruction for the fur trade is making heavy inroads upon the native stock. From 1919 to 1921 the exported pelts of a few typical animals were: opossum, 4,265,621; ring-tailed opossum, 1,321,625; koala, 208,677; wallaby, 1,722,588. There is at present no control of, or any check upon, such exports, and slaughter on such a scale can end only in virtual extermination. Some half-dozen marsupials in Western Australia are now on the verge of extinction, though their disappearance cannot readily be attributed to man's interference.

Each of the Australian States has set about protecting its own fauna in the only way in which a fauna can be adequately safeguarded, that is, by the creation of reserves in which the animals are immune from any but controlled interference. The reserves are created by the legislature, but the system of control lacks unity, in so far as it is vested in two or more independent departments of the State, while in many places the

difficulty of policing large areas with inadequate staffs plays into the hands of unscrupulous collectors. There is something to be learned, however, from the graded system which has been adopted, and of which the Western Australian reserves may be taken as examples.

Here there are four types of State-protected areas, differing a little in stability, in the primary purposes for which they were created, and in control. Class A Reserves comprise national parks, sanctuaries for native plants and animals, and cave and scenery reserves, so created that they cannot be alienated except by special Act of Parliament, an unlikely event in the present state of public feeling towards the protection of wild life. The ordinary reserves, for the preservation of the native fauna and flora, are under the control of the Ministry of Lands, and are less assured in standing, since they may be alienated by the Governor and Executive Council, without reference to Parliament. Mr. W. Catton Grasby, however, is of opinion that most of these will ultimately become permanent Of these two types, in Western Australia alone there are some forty reserves, covering in all an area of more than a million and a quarter acres. In addition to the set reserves there are forest reserves, under the Forestry Department, and game sanctuaries (thirty-six in number) under the Fisheries Department, in each of which protection is enforced.

Queensland has well over a hundred sanctuaries, including such large areas as Hinchinbrook Island (97,280 acres), Bellenden Ker Reserve (70,000 acres), and Stradbroke Island (78,720 acres); New South Wales possesses about fifty reserves, the largest of which is practically the whole of Cumberland county, with its two National Parks, specially patrolled; and each of fifteen principal sanctuaries in South Australia represents a fair-sized area of country.

The legislation adopted for the protection of native animals differs in the different States. In some (*e.g.* Western Australia) a long list of protected animals and birds is scheduled, and there even the owner of land cannot take or kill except under certain specified conditions, the general principle being laid down that all native game, whether on Crown lands or not, is the property of the Crown. Queensland, on the other hand, through its Department of Agriculture and Stock, has adopted what is known as the "black list" system, the names of non-protected creatures being listed, while emphasis is laid on the fact that all other "wild animals and birds" are totally protected throughout the whole year. Already every Queensland trapper has to obtain a permit, and every 'bird and animal' dealer a licence.

Another noteworthy step in the progress of Australian protection was marked by the passing in 1912 of a special Act for the conservation of the native flora of Western Australia. It is a model of thoroughness. Scheduled trees, shrubs and plants may not be destroyed or mutilated on Crown lands or lands reserved. No flowers that bear evidence that the plant from which they were taken was mutilated may be sold or exposed for sale. The police may examine and retain such flowers and plants, and the Government railways may refuse to carry them.

Thanks to the efforts of the Australasian Association for the Advancement of Science, the Royal Societies of South Australia and Western Australia, and other learned bodies, backed by strong public opinion, steps have been taken which should go a long way towards conserving the native fauna and flora for all time, so far as conservation lies within the power of man. These fine efforts make a strange contrast with the indifference of the British legislature to the native animals and plants of Great Britain, the existence of many of which is even more seriously threatened. The law has made not a single effort to protect our unique or disappearing plants, fishes or mammals, except in a statute, precariously renewed year by year, on behalf of the grey seal. Surely the time is approaching when the State, following the lead of its own colonies and of almost every other nation in the world, must cease leaving to private ownership the responsibility of safeguarding our native possessions, and must take steps, by creating national reserves or otherwise, to perpetuate the interesting fauna and flora as well as the notable Nature monuments of Great Britain.

JAMES RITCHIE.

The Peoples of Northern Nigeria.

The Northern Tribes of Nigeria: an Ethnographical Account of the Northern Provinces of Nigeria, together with a Report on the 1921 Decennial Census. By C. K. Meek. Vol. 1. Pp. xviii + 312 + 61 plates. Vol. 2. Pp. viii + 277 + 25 plates. (London: Oxford University Press, 1925.) 36*s*. net.

THE facts embodied in this book were for the most part collected during the census of 1921, though they have very little to do with the ideas that are commonly attached to the word 'census,' for the officers concerned were encouraged to combine with their statistical work as much ethnological investigation as was possible. Mr. Meek thus had an immense amount of territory to cover, and this presumably is the reason for the somewhat scrappy quality of much of the work, as well as the difficult and even illogical arrangement of the chapters. This said, there is little but praise for the book, which brings a large number

of new facts before the anthropologist for comparative use, and may for years be trusted to act as a dictionary which should be put in the hands of every officer in Northern Nigeria.

After a short account of the anthropo-geography of the country, extending over an area of some two hundred and fifty-four thousand square miles, the author, having mentioned some of the chief tribes, considers the 'racial elements' composing them: Negro, Hamite, Semite, with perhaps an evolving Semito-Negroid, which he thinks may in time become a definite type. The Nupe and the Yoruba are recognised as having a non-negro element, while among the negroes great diversity appears in the physical characters. Thus the brachycephalic Bantu-speaking Bafum from the Cameroons are almost pygmies, and the tall massive Jukun seem to approximate to the tall Nilotes of the Sudan. With such extremes, and with so little knowledge of the tribes, the author was probably wise to adopt a temporary classification based on language. A chapter headed "History and Tradition" is to be taken in its broadest sense; beginning with palæoliths, and including celts and arrow-heads, it continues with a discussion of objects which are certainly no later than Muhammadan times. Mr. Meek pays considerable attention to early foreign influence, and here perhaps is at his least critical: "Objects dug up in the Yoruba country by Frobenius have been dated by Egyptologists as belonging to the sixth century B.C." Again, "Egyptian goods had penetrated to Kordofan as early as 3000 B.C."; *i.e.* in common chronology, in proto-dynastic times. Surely all this requires revision? On the other hand, the author's treatment of Muhammadan history and tradition is excellent, and makes clear the complicated relations which have brought about the present condition of the northern Muhammadan states —Bornu, Kano, and Sokoto.

This roughly covers the first half of the first volume; then come chapters on technology—including an account of glass-making—followed by others on social organisation. The first chapter of the section headed "Social Organisation" is devoted to animal and plant taboos. Here the author points out that these beliefs occur among the Muslim as well as the pagans:

"Animal tabus are universal in Nigeria . . . Muslim families still have their sacrosanct animals. They are known in the *lingua franca* as *kan gidda*, which means 'the head' or 'the source of the house.' Muslims have told me that the totem witnessed the foundation of the house. They will not usually go so far as to say that their family was actually descended from the totem, but I have known professing Muslims who said that the totem contained the spirits of their forefathers. The *kan gidda* is . . . the family badge. The species is sacrosanct; it is therefore never eaten (any one inadvertently eating the flesh of his totem would immediately vomit). The revered animals are usually non-domestic, but no Zaberma will eat the camel's flesh, and the Toronkawa—a Fulani Muslim sub-tribe to which belongs the royal house of Sokoto—abstain from the flesh of goats. . . . Thus . . . in spite of their professed religion, many Muslim tribes retain a strong sense of mystic relationship with their totemic animals."

Among the pagan, perhaps the most interesting examples of animal taboos are those connected with the leopard. Thus among the Longuda—

"certain individuals who believe themselves immune from attack by leopards will refrain from eating leopard's flesh, though they will take part in a leopard hunt. A Wukari Jukun who kills a leopard parades the town with the dead animal mounted on a mat. The people salute the animal with the uplifted arm as they would a chief. Though the slayer of the leopard is given numerous gifts, he is nevertheless required to perform propitiatory rites, which include three days' solitude in the bush."

Rites indicating the royalty of the leopard also occur in East Africa; *e.g.* among the Acholi.

Mr. Meek's suggestion that the term 'animist' should be substituted for pagan does not seem very desirable, while with regard to the names of the different forms of cult of the dead, it seems doubtful whether most of these do not interdigitate in one tribe or another. A considerable number of tribes worship the sun, and of these Mr. Meek states:

"The Sun is their Supreme Deity, the All Father, the Giver of Rain, the Ripener of Crops, but so remote and otiose that he can only be approached through the host of intermediaries already described the spirits of ancestors who dwell near him, and those nature spirits who are demi-gods and his servants. He is too far removed to need the propitiation of sacrifice; but in times of stress his devotees vaguely hold out their hands to him in prayer. The Sun-worshippers seem to regard the Sun primarily as the Ripener of Crops."

The distribution of sun worship in Africa is of great interest, though too wide to be discussed here; but it is noteworthy that, while absent among the Nilotes, traces of it are to be found in the Sudan in the hill districts of Kordofan, while it is well developed in Dar Fung. In addition to the cult of numerous spirits and fetishes, and even personification of qualities (such as hunger among the Waja), the author states that all tribes recognise a supreme deity, remote and not to be approached directly; he is usually sky-dwelling, and is sometimes actually the sun; in some instances he may be considered to have charge of the souls of the dead.

The section on marriage is particularly interesting, though perhaps it is one of the most tantalising in the book; for here are given items of importance from

the marriage regulations of various tribes. Such items are of some value as indicators of custom, but not much more while they remain isolated from the social system in which they occur. However, there is much in the information that Mr. Meek has given to modify the generalisation that he himself has made on the extremely low status of women (cf. pp. 201, 204): that they are mere property to be acquired in marriage, and that the higher the bride-price the lower the status of woman, as an object to be bargained for. Among the cattle-owning tribes of N.E. and S. Africa the reverse is certainly true: a high bride-price is an honour to a woman, and so great is the esteem for cattle, so sacred their character, that the transaction of the bride-price is not really one of purchase at all. It is possible that in Nigeria, where the bride-price is usually paid in cowries or cash, it does more nearly approximate to a purchase; but from the customs that Mr. Meek quotes, it is clear that wives, though they may be inherited, are not treated as slaves, and that the bride-price acts in Nigeria, as it does elsewhere in Africa, as a guarantee of the stability of marriage. Patrilineal peoples usually consider that the bride-price secures the children for the husband, whether he is the actual father or not.

Marriage by exchange, as well as a legalised form of wife-stealing, are described. The former, by which two men exchange sisters instead of paying a bride-price, though found in other parts of the world, is rare in Africa; it has, however, been recorded among the Senoufo of the French Sudan. The function of the extended family, and its bearing on the economic life of the people, is well described. These are factors not usually sufficiently realised by administrators.

The divine character of the king is recognised in Northern Nigeria, and associated with divine kingship are those customs and beliefs that seem to be essential to high authority in Africa. The king is responsible for the rain supply, and the fertility of the land is intimately connected with the king's own virility; hence the king must not be ill or grow old, and so is killed ceremonially either before old age approaches or after reigning a definite period. The most perfect example that Mr. Meek gives is that of the Jukun. Here the king controls the rain; he is so sacred that if he touched the ground with uncovered hand or foot the crops would be blighted. At the end of seven years, at the harvest festival, the king was slain ceremonially (it is interesting to note that quite recently the Jukun chief refused to hold his festival for fear of having to submit to the ancient rite). Two women are associated with the king. One, the king's sister (in the classificatory sense), is also able to control the rain, and is treated with deference by the king himself. The other is the favourite wife of the late king, and is thus the reigning sovereign's official 'mother.' She is consulted on all important matters, and has great privileges; should she not be treated with due respect, the spirit of her late husband would take vengeance on the country. Among several other tribes the divine kingship is quite as definite, though in some cases the king himself takes poison instead of being killed. An interesting case where the rite has become symbolised is given: the Daura have a tradition of killing a dragon, but the dragon's name was Sarki, and the dragon-slayer called Ma-kas-Sarki, Hausa words for 'chief' and 'slayer of the chief.'

There is a section on languages by Mr. N. W. Thomas. The last ninety pages of the work are devoted to the census proper.

The scope of these two volumes indicates the vast amount of anthropological work that remains to be done in Nigeria, and it is to be hoped that Mr. Meek may himself be able to undertake some of it in detail.

B. Z. S.

Upper Air Phenomena.

The Uppermost Regions of the Earth's Atmosphere: being the Halley Lecture delivered on 5 May 1926. By G. M. B. Dobson. Pp. 22+4 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1926.) 2*s*. 6*d*. net.

THE publication of Dr. Dobson's Halley lecture is opportune, since it reviews, in such detail as is possible in small compass, the present state of our knowledge of the constitution of the upper atmosphere and of the chief natural phenomena occurring above the isothermal layer. Some of the phenomena, such as those due to the aurora and to meteorites, are directly visible to the eye, while others, such as the occurrence of ozone and the presence of ionised conducting layers, are appreciated by observation with special apparatus. Apart from the relation between radio and ionisation in the upper atmosphere, the public may find some interest in the fact that the natural phenomena occurring in this region are associated with an important shielding action exerted by our atmosphere, since it is the absorption of the medley of electromagnetic waves and radiations of α, β and γ type, as well as uncharged matter derived from the sun and cosmic sources, which is responsible for the effects observed. The more scientific public will welcome the publication as a concise review of the main facts in a field of endeavour to which Dr. Dobson has made extremely important contributions.

The complete interpretation of the observations demands not only a knowledge of the types of the waves, radiations and matter projected into the

atmosphere, but also of the absorbing material—the density and constitution at great heights. Neither of these two can be calculated unless the temperature is known, as well as the proportion of light gases in the lower layers.

The author deals first with the aurora and considers there is little doubt that it is due to electric discharge caused by charged particles projected from the sun, and points out that a knowledge of the nature and velocity of the radiations would enable more information to be obtained by spectroscopic means about the layers in which they are being absorbed. However, the presence of some lines due to nitrogen has been established, though the origin of the most prominent green line is still the subject of discussion and experiment in cryogenic laboratories. Reference is also made to the measurements of auroral height by simultaneous photographs from widely separated stations (illustrated by photographs), and to the faint green line observed in the light of the night sky and considered to be unconnected with the polar aurora.

The information obtained from observation of the small particles of iron or stony material known as meteors, while being vaporised by the high speed of their travel through the atmosphere, is next considered. Observation at two stations of the apparent path among the stars enables the height of appearance and disappearance, the length of path, speed and brightness to be determined. By calculation from these, it is possible to infer that the temperature of the isothermal layer (about 220° Abs.) continues to a height of some 55 km. in mean latitudes, while the temperature rises to about that at ground level above 60 km. Confirmation of a discontinuity in the atmosphere at this height is given by the fact that very few meteors disappear about the level of 55 km. The suggestion is that this rise in temperature is due to the formation of ozone from oxygen by the action of ultra-violet radiation from the sun, and by the absorption of some of the sun's rays by the ozone so formed. It is the layers ionised by ultra-violet radiation from the sun, and the electric currents set up in these ionised layers by tidal movement of the atmosphere, which are considered to be responsible for the diurnal variation of the earth's magnetic field. Reference is not made to the large variation observed at stations near the auroral zones and its great enhancement in winter on magnetically disturbed days. The importance of this observation lies in the possibility that the ionisation due to the aurora in these zones may be comparable with that due to sunlight—a matter of possible interest in the transmission of radio signals within and across the polar regions.

The author includes brief references to night luminous clouds and the propagation to great distances of the sound caused by large explosions, quoting with approval Mr. Whipple's suggestion that the temperature increase above 60 km. may be responsible for the bending down of the sound waves which have penetrated to this height.

The paper naturally does not discuss in any detail the most recent views regarding the effect of the ionised layers and their height on radio transmission. We can, however, regard it as a matter for congratulation that the increasing use of radio is likely to enhance general interest in the study of those natural phenomena which cause ionisation in the upper atmosphere.

Our Bookshelf.

Allen's Commercial Organic Analysis. Edited by Samuel S. Sadtler, Dr. Elbert C. Lathrop, and C. Ainsworth Mitchell. Vol. 4: Special Characters of Essential Oils; Resins, India-rubber, Gutta-percha, Balata, and allied Substances; the Constituents of Essential Oils, and allied Substances; the General Characters and Analysis of Essential Oils. By the Editors and the following contributors: E. K. Nelson, G. A. Russell, Ernest J. Parry, John B. Tuttle. Fifth edition, entirely rewritten. Pp. x + 648. (London: J. and A. Churchill, 1925.) 30*s*. net.

AN increase of 174 pages in this volume compared with the corresponding volume in the previous edition, published sixteen years ago, gives some indication of the advance in the chemistry of essential oils in recent years. Except for a short section of 55 pages on rubber, this book is practically confined to the subject of essential oils and resins. In its present form it is indispensable as a reference book. With a more intimate connexion between the sections than in earlier volumes, it has been possible to restrict the number of contributors so that more uniformity in the general treatment might be expected. The only British contributor is Ernest J. Parry, the well-known authority on essential oils. He has written the sections on (*a*) resins, (*b*) the constituents of essential oils and allied substances, and (*c*) the general characters and analysis of such substances. His contributions cover more than half the whole book.

The unsatisfactory arrangement in the fourth edition, with special consideration of hydrocarbons and ketones only, has been changed and a more general treatment of the subject given. Some repetition in methods and descriptions occurs and a fair number of misprints and small errors have been noticed. The statement (p. 68) that spike (lavender) oil is dextrorotatory or that West Australian sandalwood oil (p. 133) "is practically identical chemically" with oil from other sources, does not agree with the reviewer's observations. It is hoped that in later volumes improvements may be made in the index, which is not sufficiently complete for a standard reference book, while some attempt might be made to give cross-references to other volumes in the complete work.

J. REILLY.

The Sacred 5 of China is the 5th Book on China. By Dr. William Edgar Geil. Pp. xix+355+56 plates. (London: John Murray, 1926.) 24*s*. net.

As Dr. Geil's title-page indicates, he is the author of several books on China, of which "A Yankee on the Yangtze" is perhaps the best known. In explanation of his present title he says "5 is a number most remarkable to the man of the Central Kingdom." Here he deals with five sacred mountains, the peaks of East, South, Centre, West, and North—Tai Shan, Nan Yo, Sung Shan, Hua Shan, and Hêng Shan—associated with the five elements wood, fire, earth, metal, water, and the colours green, red, yellow, white and black. These mountains are all centres of pilgrimage. Of these sacred sites the importance for the student of Chinese culture lies in the fact that, like similar sites in other lands, they have been regarded as sacred from time immemorial. Like the holy wells of the British Isles, they represent a cult—and preserve survivals of it—which belongs to a stage of development infinitely more primitive than that of the official religion. So, says Dr. Geil, with the sacred mountains of China; beneath the thin rind of Buddhism, and far earlier than Confucianism, is the core with "an immemorial flavour of sanctity, the cult of the mountain spirit."

Dr. Geil, complying with the convention, ascends each mountain in five stages, but his description is not merely topographical or descriptive of the shrines and temples encountered on the way. He gives his readers a selection in each case from the legends, the history, the literature, the elements of ritual and cult associated with each peak, quoting liberally from the classics with such comment as suggests itself by the way. His book may well serve as an introduction to certain sides of the distinctive types of Chinese mentality, delicate in wit and instinct with an intellectuality peculiarly its own. The illustrations are numerous and excellently reproduced.

Die Tierwelt der Nord- und Ostsee. Herausgegeben von G. Grimpe und E. Wagler. Lieferung 2 (Teil 2. d_1, 12. h_1). Teil 2. d_1: *Noctiluca*, von A. Pratje; Teil 12. h_1: *Teleostei Physoclisti*, 10. *Heterosomata*, von W. Schnakenbeck. Pp. 12+60. 4·50 gold marks. Lieferung 3 (Teil 9. c_1, 9. c_2, 12. i_1). Teil 9. c_1: i. *Opisthobranchia*; ii. *Pteropoda*, von H. Hoffman; Teil 9. c_2: *Scaphopoda*, von Tera van Bentham Jutting; Teil 12. i_1: i. *Amphibia*; ii. *Reptilia*, von R. Mertens. Pp. 66+14+20. 7·80 gold marks. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1926.)

EACH group of animals dealt with in this new and admirably planned series is treated along definite lines; first the characters of the animals are described, then their systematic position, in some cases the best methods of fixation, the structure, the distribution, the method and powers of movement, the mode of feeding with details of the physiology of digestion and of excretion and an account of the food, the sense organs, reproduction and development, bionomics and relation to their surroundings with especial reference to parasites. Good bibliographies are provided, while excellent line drawings and maps to show the distribution illustrate the text. As a result of this mode of treatment, we are being provided with a well-balanced account of the fauna of the North and Baltic Seas, compact and yet far removed from the old-fashioned catalogues of genera and species. Points of particular interest, such as light production in Noctiluca, the growth rings on otoliths and scales in fish and the methods of marking flatfish with metal discs, are treated in detail. Further additions to this series will be awaited with interest by all workers in marine biology.

Le tremblement de terre. Par Edmond Rothé. (Nouvelle Collection scientifique.) Pp. xxxiv + 248. (Paris: Félix Alcan, 1925.) 10 francs.

M. ROTHÉ has given us in this little book a very clear account of the latest developments of seismology, especially of the instruments that have been designed for recording distant earthquakes, the methods of locating the epicentre, the forms of seismic rays, and their bearing on the structure of the earth's interior. If it were for these chapters alone, the book would be worth possessing.

The phenomena of ordinary earthquakes are treated at less length, and there are some curious omissions, but the author has wisely chosen in illustration two recent earthquakes that are not likely to lose their interest for many years to come, namely, the Chinese earthquake of 1920 and the Japanese earthquake of 1923. The book is perhaps not altogether well balanced. One could wish, for example, to see less use made of the work of Perrey, Montessus and other French authorities—fully one-third of the references are to French writers—and more to the valuable work done in Italy and Japan. The illustrations are in some cases rough and poorly reproduced, and it is difficult to see the use in a scientific text-book of pictures of Tokyo in flames or of heaps of corpses lying about the streets of the city. The preface, it may be added, contains a brief, though interesting, outline of the history of seismology. C. D.

Migraine and other Common Neuroses: a Psychological Study. By Dr. F. G. Crookshank. (Psyche Miniatures, Medical Series, No. 1.) Pp. 101. (London: Kegan Paul and Co., Ltd., 1926.) 2*s*. 6*d*. net.

THE average general practitioner has little time and opportunity for the study of text-books on the complicated, and in these days bewildering, subject of psychotherapy. To him, therefore, will be of especial value the publication of Dr. Crookshank's two lectures on migraine and other common neuroses. The book is a small one; it can be read in an hour, and the author's style is delightfully attractive. His views—even as expressed in the title—will, of course, arouse controversy, and some of his statements can be described only as startling. His reasoning that the mind may be the deciding factor in the etiology of dementia paralytica, because mental symptoms usually precede the appearance of physical signs, is unconvincing. Yet there is nothing in these pages which the neurologist or psychologist could dogmatically deny; and if the author's efforts to demonstrate the supremacy of the psychological factor in migraine should only turn the attention of physicians to the psychical aspect of all who are sick, the book will have served its purpose.

Letters to the Editor.

X-Rays—Internal Absorption and 'Spark' Lines.

IN recent work by Mr. A. M. Cassie and myself (now being prepared for publication), it has been possible to study some of the details of the process of 'internal' absorption of an X-ray by the atom in which it is excited. This type of absorption has played an important part in the elucidation of β- and γ-ray spectra, and has been fully discussed, notably by Ellis and Skinner in Great Britain, and by Meitner, de Broglie, Thibaud, and others. An excellent summary of the work on the X-ray side is to be found in Bothe's article in vol. 23 of the new Geiger and Scheel "Handbuch."

In the X-ray domain the effects of internal absorption have been beautifully demonstrated by P. Auger in his Wilson tracks produced by X-rays in heavy gases. Auger's results show that in the K excitation of argon, about 90 per cent. of the fluorescent K quanta are absorbed by the atoms in which they are excited, with emission of tertiary photoelectrons: this "specially privileged" absorption becomes less marked with heavier elements (about 50 per cent. for krypton, and, according to Meitner, about 10 per cent. for elements of atomic number round 85), but is in any case amazingly high.

In our experiments, the secondary cathode rays emerging from a 'target' irradiated by X-rays are drawn out into a magnetic spectrum, and their energies are measured as in earlier work by de Broglie, Whiddington, Robinson, and others. In the present work a great deal of 'white' radiation is allowed to remain in the X-ray beam, and in consequence the fluorescent X-ray spectrum of the target is strongly excited. The corpuscular spectra show many lines which are due to the internal conversion of the fluorescent X-rays, or, alternatively, to radiationless (Rosseland) readjustments within the atom which lead to the expulsion of 'photoelectrons of the second kind.' For brevity these lines may be called 'fluorescent' lines, to distinguish them from the 'normal' lines arising from the external absorption of the constituents of the primary X-ray beam.

There are very many of these fluorescent lines, some of them very faint and difficult to resolve, and the measurements are not yet complete. It is certain, however, that most of these electrons emerge with considerably less energy than would be expected if they came from a normal atom: the deficiency is of the order 50-100 electron-volts—far too big for experimental error. There can be little doubt that they come from atoms which were already ionised, and, therefore, had abnormally high energy levels. This energy defect would be inappreciable in a fast β-ray, and scarcely detectable from the Wilson tracks.

The processes taking place are easily visualised; for example, as a possible sequence we may have in successive stages following the ejection of a K electron from the target—(1) an L_{III} electron falling into the vacant place with emission of a $K\alpha_1$ quantum of fluorescent X-radiation; (2) internal absorption of this quantum, with expulsion of a photoelectron from an L, M . . . shell, either while the vacant place in L_{III} is still untenanted, or after L_{III} has been completed (say by an M electron), but while the atom is still ionised in an outer shell. This is typical of many possible processes of the same kind (cf. Auger, *J. Phys. et le Radium*, June 1925), all leading to atoms which are multiply ionised in their X-ray shells. So far as the final result is concerned, it is immaterial whether this takes place as above, or by way of radiationless changes.

The multiply ionised atoms produced in this way ought to be competent to account for at least some of the abnormal lines observed in nearly all X-ray spectrograms (Coster's 'non-diagram' or Wentzel's 'spark' lines) as faint satellites on the high frequency sides of the series X-ray lines. Wentzel has worked out in detail the theory of these 'spark' lines, on the assumption that they are due to multiply ionised atoms. While there can be no doubt of the essential accuracy of Wentzel's work, the experimental evidence as to the manner in which the multiple ionisation is brought about is still very unsatisfactory (cf. Bäcklin, *Zeit. für Physik*, **27**, p. 30). Dr. Wentzel suggested to me some time ago that my corpuscular spectra might show traces of multiple ionisation produced by a single X-ray quantum, but so far I have got no evidence of this (in any case these lines would be very faint). Internal absorption obviously could not account for the production of spark lines in the K series; that is, it could not be expected to produce atoms in the K^2, KL . . . conditions required by Wentzel—but it certainly could account qualitatively for the existence of L spark lines. As shown in the above example, once the K excitation limit is reached, there will be large numbers of atoms in L^2, LM . . . conditions: this provides a very satisfactory explanation of the effect observed by Siegbahn and Larsson (*Ark. Mat, Ast. och Fysik*, **18**, 1924). These experimenters, investigating the L spectrum of molybdenum with a tube operated at different voltages, found no new spark lines between 4 and 20 kilovolts. At 20 kv. a new line first appeared, and no further line appeared even at 40 kv. 20 kv. is just more than is required to excite molybdenum K, and is certainly insufficient for simultaneous K, L ionisation.

We have obtained direct and very striking evidence of the fundamental difference between internal and external absorption, by experiments in which a thin copper target was exposed under identical conditions to (1) copper $K\alpha_1$ primary rays and (2) white radiation from a molybdenum tube operated at high voltage. In case (1) we get the normal copper L lines, L_I and (L_{II}, L_{III})—the latter pair as an unseparated doublet—resulting from external absorption of the primary copper $K\alpha_1$. In case (2), following the ejection of a K electron, we have internal absorption of the same quantum. The corresponding L lines of the 'fluorescent' spectrum are definitely displaced 0·6 mm. (about 60 to 70 volts) on the plates in the direction of smaller energy, and there is no visible trace of the 'normal' lines. Further—and this is most significant—the intensity ratio is entirely changed: with external absorption of $K\alpha_1$, L_I is slightly more intense than (L_{II}, L_{III}) (cf. Robinson, *Roy. Soc. Proc.*, 1923). In case (2) the doublet (L_{II}, L_{III}) is by far the more intense.

Similar effects have been noticed in β-ray spectra, but in our experiments the phenomenon is naturally under greater control, and the interpretation more direct.

A New Type of Absorption Spectrum: Double Rotational Quantification in Formaldehyde.

THE quantification of the rotational motion of an assymmetrical molecule having three different moments of inertia, J_0, K_0, L_0, is a very difficult problem and has not yet been resolved mathematically. However, if two of the moments are equal, $K_0 = L_0$, the problem lends itself to solution, as has been shown by Sommerfeld, Born, Reiche, and others. The rotational energy of a molecule having an axial symmetry is equal to

$$W_{m,q} = \frac{h^2}{8\pi^2}\left[\frac{q^2}{K_0} + m^2\left(\frac{1}{J_0} - \frac{1}{K_0}\right)\right],$$

where m and q are quantum numbers.

The absorption lines corresponding to the different possibilities of rotational transitions of a molecule of this kind form a very complicated spectrum. This may be represented by the juxtaposition of two systems of parabolic branches:

$$\text{I.}\quad \left.\begin{array}{ll} R(m) = \nu_0 + (c_0 + c_1)m + c_2m^2, & \ldots\ m - \tfrac{1}{2} \rightarrow m + \tfrac{1}{2} \\ P(m) = \nu_0 - (c_0 + c_1)m + c_2m^2, & \ldots\ m + \tfrac{1}{2} \rightarrow m - \tfrac{1}{2} \\ Q(m) = \nu_0 + c_2m + c_2m^2 & \ldots\ m + \tfrac{1}{2} \rightarrow m + \tfrac{1}{2}, \end{array}\right\} q = \text{constant},$$

where

$$c_0 = \frac{h}{8\pi^2 c}\left(\frac{1}{J_0} - \frac{1}{K_0}\right),\ c_1 = \frac{h}{8\pi^2 c}\left(\frac{1}{J_1} - \frac{1}{K_0}\right),$$
$$c_2 = c_1 - c_0,\ c = 3 \times 10^{10}\ \text{cm.}$$

$$\text{II.}\quad \left.\begin{array}{ll} R(q) = n_0 + (\sigma_0 + \sigma_1)q + \sigma_2q^2, & \ldots\ q - \tfrac{1}{2} \rightarrow q + \tfrac{1}{2} \\ P(q) = n_0 - (\sigma_0 + \sigma_1)q + \sigma_2q^2, & \ldots\ q + \tfrac{1}{2} \rightarrow q - \tfrac{1}{2} \\ Q(q) = n_0 + \sigma_2q + \sigma_2q^2, & \ldots\ q + \tfrac{1}{2} \rightarrow q + \tfrac{1}{2}, \end{array}\right\} m = \text{constant},$$

where

$$\sigma_0 = \frac{h}{8\pi^2 c}\cdot\frac{1}{K_0},\ \sigma_1 = \frac{h}{8\pi^2 c}\cdot\frac{1}{K_1},\ \sigma_2 = \sigma_1 - \sigma_0$$

Hitherto, no one has reported an absorption spectrum of this kind, and it is not known if there may exist a double quantification of the rotation of molecules.

We have found that the ultra-violet absorption spectrum of formaldehyde vapour,

H H
C
O

, corresponds exactly to this type of rotational spectrum, with two quantifications.

The absorption spectrum consists of 32 bands situated between 3550 and 2500 Å.U. Each of these bands is formed by hundreds of fine lines. These lines are of two types: type *a* consists of the more intense lines distributed through the whole band. The other type, *b*, consists of a great number of very fine, closely grouped lines forming regular series with accumulations near each line of type *a*.

The molecule of formaldehyde has, to a first approximation, an axial symmetry about the axis passing through the carbon and oxygen atoms. The moment of inertia, J_0, about this axis is expressed by $J_0 = 2 \cdot r^2_0 \cdot m$, where $2r_0$ is the distance between the two hydrogen atoms, and $m = 1{\cdot}66 \times 10^{-24}$ gm. The other two moments, K_0 and L_0, have very nearly the same value. This value depends upon the distance between the carbon and oxygen atoms, and upon the angle, 2α, between the bonds of the hydrogen atoms to the carbon atom, so that $K_0 \gg J_0$.

The physical interpretation of the spectrum is that the stronger lines (type *a*) are produced by rotation about the axis of symmetry, with the smaller moment J_0. The closely grouped fine lines (type *b*) correspond to the rotations about a perpendicular axis with the moment K_0.

The analysis of the distribution of the lines in the different bands has given a very satisfactory confirmation of this interpretation. We have found, for example, for the band $B(\lambda = 3418$ to $3378)$ that the stronger lines form a doublet system of three parabolic branches each, the null-lines being $\nu_0 = 29465{\cdot}1$, $\nu'_0 = 29422{\cdot}0$, $\lambda_0 = 3393{\cdot}85$, $\lambda'_0 = 3398{\cdot}82$ Å.U. intern. vac., and the formulæ of the parabolas

$$\begin{aligned} R(m) &= 29465{\cdot}1 + 35m - 2m^2, \\ P(m) &= 29465{\cdot}1 - 35m - 2m^2, \\ Q(m) &= 29465{\cdot}1 - 2m - 2m^2, \\ R'(m) &= 29422{\cdot}0 + 35{\cdot}5m - 1{\cdot}5m^2, \\ P'(m) &= 29422{\cdot}0 - 35{\cdot}5m - 1{\cdot}5m^2, \\ Q'(m) &= 29422{\cdot}0 - 1{\cdot}5m - 1{\cdot}5m^2, \end{aligned}$$

where $m = 1, 2, \ldots 8$. The correspondence between the calculated and the observed values is very good (Δ'_λ calculated − observed $\pm 1{\cdot}0$ cm.$^{-1}$). The distribution of the intensities is also quite regular and conforms to the theoretical one.

We deduce from these formulæ the following values for the constants:

$$c_0 = 18{\cdot}5,\ c_1 = 16{\cdot}5,\ c'_1 = 17{\cdot}0,$$

and therefore

$$= 0{\cdot}67 \times 10^{14},\ \frac{1}{J_1} - \frac{1}{K_1} = 0{\cdot}60 \times 10^{+40},$$
$$\frac{1}{J'_1} - \frac{1}{K_0} = 0{\cdot}62 \times 10^{+40}.$$

A series of lines of type *b*, distributed in parabolic branches $R(q)$ and $P(q)$, correspond to each line of these six parabolic branches. The value of $\sigma_0 + \sigma_1$ is $2{\cdot}4$ cm.$^{-1}$ with a precision of $\pm 0{\cdot}4$ cm.$^{-1}$.

We have, therefore, $\frac{1}{K_0} = 0{\cdot}04 \times 10^{+40}$.

The two moments of inertia of the normal molecule of formaldehyde are $J_0 = 1{\cdot}41 \times 10^{-40}$ and $K_0 = 25 \times 10^{-40}$. Therefore, the distance between the hydrogen atoms is $2r_0 = 1{\cdot}30 \times 10^{-8}$ cm., and between the carbon and oxygen $1{\cdot}0 \pm 0{\cdot}1$ Å.U. In the molecule of water the distance between the hydrogen atoms is $1{\cdot}64$ Å.U., and in the carbon dioxide molecule the distance between the carbon and oxygen atom $1{\cdot}02$ Å.U.

For the activated molecule we find two values of the moments of inertia: $J_1 = 1{\cdot}56 \times 10^{-40}$ and $J'_1 = 1{\cdot}51 \times 10^{-40}$. The branches R, P, Q correspond to the transitions from the normal energy level to the state with the moment J_1, and the branches R', P', Q' to the transitions from the same normal state to the energy level with the moment J'_1. The distance between the hydrogen atoms is increased by the activation from $1{\cdot}30$ to $1{\cdot}37$ Å.U.

This general structure of a rotational spectrum with two simultaneous quantifications has been observed by us for several other molecules belonging to the type of 'Y-molecules'; for example, phosgene and thiophosgene. Together with Prof. J. Errera, we have found the same type of absorption spectra for different para-derivatives of benzene.

Surveys of the Great Pyramid.

IN an article in NATURE of December 26, 1925, Sir W. M. Flinders Petrie compares unfavourably the recent survey of the Great Pyramid carried out by Mr. J. H. Cole, of the Survey of Egypt, with his own survey of 1881. He points out that the closing error in the eight angles of Mr. Cole's traverse around the pyramid, which amounts to 9·6 inches, is equal to a difference of 2·7 inches "if on the whole distance." This statement would only be relevant to his argument if the traverse were an open one run, more or less, in a straight line, and if the angular error were located entirely in the initial angle. In fact, when the measured quantities (angles and lengths) are taken as observed, the closing error of the traverse amounts to 0·7 inch, and when the traverse is adjusted to self consistency, the greatest corrections applied are 0·04 inch to a measured length and 2·7 inches to an observed angle.

In Sir Flinders Petrie's book, "The Pyramids and Temples of Gizeh," he explains in Appendix II. the methods he used for determining the precision of his work and for weeding out "occasional errors." In the example he gives, on page 230, the four observations he rejects would have been retained by such authorities as Wright and Hayford or Brunt, who only reject observations the residuals of which are at least five times as great as the probable error of a single observation, unless there are physical reasons (wrong sightings, movement of instrument, etc.) for doubting the work. In the 1881 survey, out of 108 sides of triangles around the Great Pyramid, the mean observations of no less than nine were rejected. This excessive number of rejected observations should never have been tolerated

I have little doubt that the high precision claimed by Sir Flinders Petrie has only been obtained by the unwarranted rejection of observations with large residuals, which has decreased his computed probable error but at the same time has certainly diminished the precision of his results.

Mr. Cole's survey has now been tied up to points O, Q, and W of the 1881 survey. The bronze bolt U has gone but another bolt has been leaded into the same hole in the floor of the south-east corner socket and must agree within half an inch with point U. When the two surveys are fitted together by means of the points common to both, Sir Flinders Petrie's point on the casing edge on the east of the pyramid falls 2·7 inches to the east of the casing edge as surveyed in 1925. The other three points on the casing edge agree within one inch.

Accepting the accuracy of Mr. Cole's survey as deduced from the closure of the traverse, and from our knowledge of the precision of the methods employed, this large discrepancy on the east can only be attributed to an error in the 1881 survey.

In the course of this investigation several discrepancies in Sir Flinders Petrie's work have come to light. For example, the eastern side of the Great Pyramid is given as 9067·7 inches. On Plate X the N.E. socket corner is stated to be 30·2 inches north and the S.E. socket corner 35·5 inches south of the corresponding pyramid corners The eastern socket side should therefore be 9133·4 inches and not 9130·8 inches as given.

Mr. Cole's survey was an attempt to determine the exact shape and size of the pyramid as it was built. Sir Flinders Petrie, on the other hand, reconstructed the pyramid as, in his opinion, it should have been built. He remarks "we only need to compute a square that shall pass through the points of the casing found on each side, and having also its corners lying on the diagonals of the sockets."

This being the case, there is nothing to be gained by dealing with Sir Flinders Petrie's arguments published in NATURE. However, his statement that "it would be easier to achieve equality of length than of level" is, in my opinion, not true.

I therefore conclude that Sir Flinders Petrie's survey of 1881 is not nearly so accurate as he claims, that it contains errors amounting to so much as two inches, and that Mr. Cole's survey, whatever slight inaccuracies it may possess, is the most precise survey of the Great Pyramid that has yet been made.

I agree with Sir Flinders Petrie that it is highly desirable that a survey should be made joining the existing casing edge on to lines laid out close to the base, but this will have to wait until several thousands of tons of debris have been cleared away. I hope this will be done in the near future.

F. S. RICHARDS,
Director, Computation Office.

Survey of Egypt,
El-Giza (Mudiriya),
June 12.

THE first point raised by Mr. Richards refers to my remark that the method of placing a single triangle of survey round a pyramid (as in the 1881 survey) was better than a line of eight lengths of traverse carried on by dead reckoning round the base, as in 1925. The effect of the error being possibly caused in the first of the eight angles, was only stated by me to illustrate the unsatisfactory principle of the method

The exclusion of anomalous observations of five times the probable error is held up as a pattern That would be true enough on a series of 4000 observations. On a series of 100 the limit of normal variation would be much smaller. No arbitrary rule should be followed. I excluded anomalies, one by one, until the whole series became almost normal in distribution. I still think that this is the probable road to the truth. The casual causes were due to lateral lighting and refraction of hot air I prefer not to vitiate results by including anomalies, which are detected by the distribution of errors.

The points O, Q, W, in common on the surveys of 1881 and 1925, are stated to have been now fitted together (without quoting a difference), and the only difference is on a point plumbed up from a deep hole in 1881, which was by no means the same place as was fixed and seen on that base side in 1925. The discrepancy pointed out between the socket length and the base side which was deduced from it, on the east, is due to some misprint or slip in mere addition, and has nothing to do with the accuracy of survey. There is, therefore, no ground for claiming that there are errors amounting to two inches in the 1881 survey.

FLINDERS PETRIE.

Magnetic Susceptibilities and Dielectric Constants in the New Quantum Mechanics.

IT is well known that the conventional quantum theory must be modified in accordance with the matrix dynamics developed by Born, Heisenberg, and Jordan, and by Dirac. The purpose of the present note is twofold, namely: (1) to show that in the new theory the spacial quantisation relative to the applied field has no direct effect on the magnetic susceptibility (or the dielectric constant), and (2) to give the results of the calculation of the dielectric constant of a diatomic gas by means of the new mechanics.

(1) It has been generally supposed that in a gas or liquid the orientation of atoms or molecules is random in the absence of a field, and that consequently there may be a change in the susceptibility when the field exceeds the critical value requisite for spacial quantisation. We shall show, however, that in the matrix theory the susceptibility is the same with spacial quantisation relative to the applied field as with random orientations. Let us first suppose the magnetic body is composed of atomic rather than molecular aggregates (*e.g.* monatomic ions in solution). If a magnetic field is applied along the z-axis, the paramagnetic susceptibility per atom is proportional to the average value of M_z^2/kT, where M_z is the z-component of the resultant angular momentum M. With spacial quantisation we have $M_z = mh/2\pi$, and, if j denotes Sommerfeld's inner quantum number, there are $2j+1$ possible orientations. The average value of M_z^2 is then

$$\frac{1}{2j+1}\sum_{m=-j}^{+j}\frac{m^2h^2}{4\pi^2} = \frac{1}{3}j(j+1)\frac{h^2}{4\pi^2} = \frac{1}{3}M^2,$$

which is obviously the same result as with random orientations. Although the ordinary Langevin formula is thus still applicable even with spacial quantisation, the numerical values of susceptibilities are the same as those calculated by Sommerfeld with the older quantum theory, for his correction factor for the effect of spacial quantisation is the same as the factor by which M^2 differs from $(jh/2\pi)^2$ in the new theory.

The preceding argument can be extended to show that spacial quantisation does not change the susceptibility of paramagnetic molecules, diamagnetic susceptibilities, or the dielectric constant of molecules with an electrical moment, such as HCl. This perhaps explains why Lehrer (*Zeits. f. Phys.*, **37**, 155, 1926), on repeating Glaser's experiments, finds no variation of the diamagnetic susceptibility of argon or carbon dioxide with pressure, and especially why the dielectric constants of polar gases do not ordinarily vary with the pressure or field-strength despite the fact that at atmospheric pressure the intervals between collisions are small compared to the precession period.

(2) Let us suppose we have a non-gyroscopic diatomic molecule with an electrical moment μ in the direction of the axis of figure. Using the amplitude matrices for the rotating dipole given by Miss Mensing (*Zeits. f. Phys.*, **36**, 814, 1926), or by Dennison (*Phys. Rev.*, August 1926) we can calculate the dielectric constant with the perturbation methods developed by Born, Heisenberg, and Jordan. The remarkable result is obtained that only molecules in the state $j=0$ of lowest rotational energy make a contribution to the polarisation This corresponds very beautifully to the fact that in the classical theory only molecules with energies less than μF contribute to the polarisation (Alexandrow, *Phys. Zeits.*, **22**, 258, 1921).

The formula for the polarisation takes the simple form

$$P = \frac{8\pi^2 I\mu^2 F}{3h^2}n(T),$$

where F is the field-strength, I is the moment of inertia, and $n(T)$ is the number of molecules in the lowest rotational state. Here and elsewhere we use the term polarisation in the restricted sense of meaning only the part of the actual polarisation which is attributable to the permanent moment of the dipoles. There is, of course, in addition the 'induced' or 'electronic' polarisation, which is approximately the same for all rotational states and hence independent of the temperature. The ratio of $n(T)$ to the total number N of molecules is given by the Boltzmann formula, and from the asymptotic value of this ratio it follows that at high temperatures our formula for P reduces to the Langevin expression $N\mu^2F/3kT$. This is a much more satisfactory result than in the older version of the quantum theory, in which both the calculations of Pauli with whole quanta (*Zeits. f. Phys.*, **6**, 319, 1921) and of Pauling with half quanta (*Phys. Rev.*, **27**, 568, 1926) yielded results diverging from the classical Langevin theory even at high temperatures.

Similar calculations can be applied to the paramagnetism of molecules, expect that is probably necessary to suppose the molecule gyroscopic. The formula for the susceptibility is then more complicated, as it contains contributions from all the rotational states, but still reduces to the Langevin formula at high temperatues. Details of the calculations will be published elsewhere.

The Attractions of the Ends of Chromosomes in Trivalents and Quadrivalents.

I HAVE lately investigated the chromosome configurations at the metaphase of the first division in the pollen mother-cells of about sixty species and varieties of plants (including triploids, tetraploids, and $2n+1$ forms). The method used guaranteed perfect fixation, and the homologous chromosomes were usually clearly distinguishable at the metaphase. The following facts have been observed (omitting those few plants in which the pairs of chromosomes at the reduction metaphase were joined elsewhere than at the ends):

(1) In diploids (upper line of Fig. 1) the two

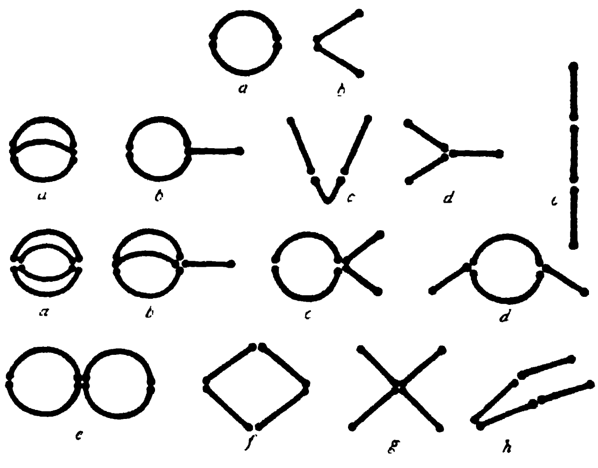

FIG. 1.—Configurations of chromosomes found in diploid, triploid, and tetraploid sets, at the first metaphase of the maturation divisions in the pollen mother-cells.

homologues are nearly always joined at both ends (a). Those joined only at one end (b) are rare.

(2) In triploids (second line of Fig. 1), c is the most common configuration, and together with b and d forms the bulk of the configurations; a being quite rare. This shows either that the combination of *two* chromosome ends is more stable than the combination of *three*; or that the attractions of the chromosome ends are partly neutralised by contact, so that when two ends are combined there is less attraction for a third. Thus the greater number of the junctions in the trivalents are of two chromosome ends, not of three; and in consequence free ends are common.

(3) In quadrivalents (lower two lines of Fig. 1), *e* is the most common form, *b*, *c*, *d*, and *f* being rare. Thus junctions of two ends are as common as those of four or three, and free ends are abundant.

(4) In agreement with these results is the fact that the frequency of separate single chromosomes at the first metaphase is least in the diploids, where they are rare. It is greater in triploids, where separate chromosomes may sometimes occur almost in every other cell. In tetraploids, however, separate chromosomes are usually so common that it often requires a search to find a cell with *n* quadrivalents.

Scientific Neglect of the Mas d'Azil.

THE other day in the course of an automobile tour I visited the Mas d'Azil. I would like to direct the attention of the readers of NATURE, and particularly of those with money and organising power, to the very unsatisfactory state of affairs in this beautiful and incomparable treasure-house of archæological material. Practically there is no control, no protection and no organised excavation whatever at Mas d'Azil. There are masses of valuable material, but none of it is being worked at properly. Much of it, I fear, is being wasted and muddled up. There is a 'guide,' a pleasant untrained man, who pokes about in the caves, digs out bones which, as he remarks, fall to pieces, and presents the casual visitor with teeth or flint implements he has found in his own researches. He has no regular salary. He has to supplement his fees and tips by other work. Occasionally, isolated individuals obtain permission from the municipality and prod in the rocks and extract this or that and publish their 'results,' according to their lights. There is a small useless museum without labels or arrangement at the Mairie. The financial situation forbids the hope of Government direction. The essential trouble seems to be the want of funds. From Mas d'Azil came some of the most beautiful and interesting objects in the admirably arranged museum in Toulouse; the carved horse head and other carvings and the painted pebbles from this site are well known. One would not need to go outside the scientific ability available in the region if money were forthcoming to mobilise it for the proper exploitation of these priceless deposits.

H. G. WELLS.

The Eggs of the Pilot-fish (*Naucrates ductor*).

IN *Ann. Mag. Nat. Hist* (9) 2, p. 114, 1918, Dr. Gilchrist described the egg of the Pilot-fish as having a long filament attached to the pole opposite the micropyle, and he states that it serves to attach the egg to the wall of the ovary. Further, the egg was stated to be oval, with a large perivitelline space, but without any oil globule. From the presence of the filaments on the eggs, Dr. Gilchrist presumed that the eggs were attached to floating objects and offered a plausible explanation of the well-known, but hitherto unexplained, habits of the Pilot-fish.

In November last a ripe female of the Pilot-fish was received at this Museum, and I was able to obtain a large quantity of eggs. To my astonishment these eggs differed from those described by Dr. Gilchrist in the two main characteristics mentioned: they possessed no trace of any filaments, but a distinct oil globule was present. On the other hand, they agreed in their more or less oval shape and the large perivitelline space. They floated in sea water. An examination of the ovary disclosed no "grape-like clusters" such as Dr. Gilchrist found, but only the normal structure.

In the case of such a well-known fish as the Pilot-fish, misidentification can be excluded. Another very unlikely possibility occurred to me, namely, that by a slip of the pen *Naucrates ductor* was written instead of *Echeneis naucrates*, the latter fish also being known in these waters as 'Lootsman' and found in association with sharks. To be certain, I examined the Museum material of this and allied species, the eggs of which are apparently still undescribed. Only two females with ripe ova were found and these lent no support to the suggestion of a misnomer having occurred. The ovary showed normal structure and the loose ripe eggs showed no trace of filaments.

The explanation of these diametrically opposed observations can only be found by the study of further material, and it is in the hope that ichthyological students will take the opportunity of examining fresh material and material preserved in Museums, that this letter is written.

Spinning Electrons.

IN view of the recent correspondence in NATURE concerning the spinning electron, it may be of interest to consider the effect of free electrons possessing a magnetic moment on the magnetic susceptibility of metals.

If the magnetic moment of the free electron is one Bohr magneton, and the orientation of its axis with respect to an external magnetic field is assumed to be given by the Boltzmann distribution law, then the paramagnetic contribution to the molecular susceptibility (on the basis of the Pauli-Sommerfeld averaging) will be $1378 \times 10^{-6} P$ at 273° K, where P is the ratio of the number of free electrons per gram-molecule to Avogadro's number. Copper and silver have molecular susceptibilities of $-5{\cdot}7 \times 10^{-6}$ and $-20{\cdot}5 \times 10^{-6}$ respectively. The contribution to the diamagnetic susceptibility of such atoms or ions as may exist in the metal can scarcely be more than $-29{\cdot}8 \times 10^{-6}$ (the molecular susceptibility of Rb^+) in the case of copper, and -37×10^{-6} (Cs^+) in silver.

It must be remembered, in addition, that the normal atom in copper and silver has a magnetic moment of one Bohr magneton. Unless we assume that in the solid metal these elements exist in a form very different from their normal atomic state, and further, that the number of free electrons does not exceed 3 per cent. of the total number of atoms, the hypothesis of the spinning electron leads to some difficulties in understanding the diamagnetism of these metals, and of the alkalis as well.

Since the contribution to the susceptibility of the spinning free electrons would obey the Curie law, namely, that the paramagnetic susceptibility is inversely proportional to the absolute temperature, any considerable contribution to the susceptibility would therefore show itself in a temperature variation in the total diamagnetic susceptibility of a much higher order than that actually found by experiment.

Biology and the Training of the Citizen.[1]

By Prof. J. GRAHAM KERR, F.R.S.

I PROPOSE in this address to depart somewhat from precedent, and to devote it neither to a general review of recent progress in our science, nor to the exposition of my own special views on problems of evolutionary morphology, but rather to a more general subject—one which I believe to be at the present time of transcendent importance to the future not merely of our nation but, indeed, of our civilisation—namely, the relation of biology to the training of the future citizen. Speaking as I do from this chair, I need scarcely say that by biology I mean more especially animal biology.

It is unnecessary to emphasise at length the enormously important part which biological science plays in the life of our modern civilised state. The provision of food for the community—crop-raising, stock-breeding, the production of dairy products, fisheries, the preservation of food by canning and freezing, and so on—is obviously an immensely complicated system of applications of biological science. So also with the maintenance of the health of the community—the prevention of disease, much of which is now known to be due to the machinations of parasitic microbes, often transported and spread by other living organisms, and the cure of disease by the modern developments of medicine and surgery—these again are applications of biological science. When we contemplate merely such simple facts known to everyone, when we see to what an extent the results of biological science are woven in and out through the whole complicated fabric of modern civilisation, when we contemplate further the gigantic expenditure in money devoted to the school training of our future citizens, it must surely strike us as an extraordinary fact that biological science enters scarcely, if at all, into the school training of our average citizen.

What I have said indeed applies, if only in lesser degree, to the subordinate position occupied by science as a whole in our school training. In the early stages of human evolution, as we see illustrated on the earth of to-day by those comparatively primitive savages who still remain in the nomadic hunting phase, what we should now call science plays an all-important part in the education of the young individual: he is taught to observe accurately the phenomena of Nature, dead and living, to draw the correct conclusions therefrom, and to regulate his actions accordingly. In our own early history, science undoubtedly played an equally important part in the training of the young. Even down into the Middle Ages it supplied an appreciable part of the curriculum of the educated man, the seven liberal arts of these days containing a large infusion of what we now call science. In later times, however, from the renaissance of classical learning onwards, science has been kept in the obscure background of our educational curriculum, and in spite of much tinkering of detail in recent years, that curriculum continues unchanged in its main features: it remains preponderatingly literary and classical. Even to-day, if we listen to contemporary discussions on education, we commonly hear arguments as to the relative merits of different constituents of the current curriculum, but the general framework of that curriculum seems to be regarded as sacred from all interference.

Yet these recent years have witnessed the most tremendous advances in the evolution of our social organisation, and, as the position now is, it seems as certain as anything can be that unless further advance is accompanied by a corresponding evolution in the training of our future citizens, a condition of instability will soon be reached such as to involve the risk of complete disaster. Probably the factor in our modern social evolution which has brought in its train the greatest danger is the development of what in general terms we may call means of intercommunication—the means by which transport is effected—on one hand of material things, on the other hand of ideas. Primitive man in the hunting phase of his evolution is a nomad, but a nomad within a restricted area: his wanderings are limited by the more or less vague boundaries between his own territory and that of neighbouring tribes. He is entirely dependent for food and raiment upon what Nature provides within these limits: he knows little of the world beyond except that it is peopled by strangers of varying degrees of hostility: his code of ethics is limited by the same boundaries—highly developed as regards intercourse with his own tribe it ceases to exist in his intercourse with those outside. His dominating idea is loyalty to his own kinsfolk and fellow tribesmen, and for this idea he is ready to make any sacrifice.

With advancing evolution, when the communal unit is no longer the clan or tribe but the nation or federation of nations, geographical and political boundaries still exist; but with the evolution of means of transport by road and rail and sea they cease to form impassable barriers—men and goods are able to pass them freely. Of even greater moment to citizenship than the transport of material things is the transmission of ideas. The great developments in this have come about in the first place with the evolution of language, the vehicle of thought, which has rendered possible the transmission of thought from individual to individual. The use of visible material symbols of a lasting kind—whether pictorial or simply conventional, as in modern writing and printing—while facilitating still further the transmission of thought from individual to individual and from place to place, has done far more, for it has enabled the achievements of each generation to be handed on to its successors with a completeness that was quite impossible by the merely spoken word.

While these advances in the methods of transmitting thought have played an all-important part in rendering secure the orderly progress of human knowledge, they have brought in their train, curiously, one of the most potent disturbing factors to the progress of communal evolution. This disturbance is brought about through interference with the workings of one of the great principles of communal evolution—that of leadership.

[1] From the presidential address to Section D (Zoology) of the British Association delivered at Oxford on August 6.

LEADERSHIP.

Already in the primitive tribal community we find this factor at work. Tribes differ in their size and power—their men may number a mere half-dozen or several hundreds—and the main factor in this is the personality of the tribal chief. Among his own men the chief stands out by his capacity, mental and physical: a quick and accurate observer, he is also quick and accurate in drawing his deductions: he is wise, he is rich in knowledge and in its bearings; while alert and quick in decision, he is of steady nerves, has a good sense of balance, and is reliable in emergency. So it is onwards through historical evolution—the chief, the ablest man of his tribe, finds his successors in a long sequence of natural leaders of men.

It is the more modern developments concerned with the transmission of thought—printing, telegraphy, radio telephony, kinematography, and so on—that constitute the great disturbing factor, inasmuch as they have given enormously increased importance to elements of individual personality quite distinct from general strength and capacity, mental and physical. Amongst such elements there stand out conspicuously oratorical power and skill in the method of advocacy. The leader is no longer forced to the front by the sheer power of his outstanding constructive ability; the place of this is to a great extent taken over by the power of effective and persuasive writing and speaking. The most responsible posts in the leadership of the modern State have been rendered accessible to the skilled orator, even though his constructive ability in statesmanship may not be of the highest.

That this development involves serious dangers is obvious; it seems equally obvious that one of the main tasks confronting the community is the devising and setting up of the educational safeguards which alone can be efficient against these dangers. The task will, indeed, be no easy one: it will clearly, for its satisfactory accomplishment, call for the best intellects the community can provide. However great the ability of those to whom the task is entrusted, it will prove one of high complexity and much difficulty; but certain inevitable conclusions seem to be visible, one of the chief of these being the need of drastic cutting down of the number of subjects at present inflicted upon the young citizen in training during his school period. How exactly this is to be done will have to be worked out carefully; but it seems clear that at present an immense amount of time is given, during the early stages of the curriculum, to subjects which might profitably be replaced by others of greater value in mind-training during these earlier stages. If postponed to a later stage of mental development, such subjects can be mastered in a small fraction of the time required in the earlier stages—when, by the way, their prolonged and wearisome study is but too apt to kill effectively all interest on the part of the pupil in the particular subject.

While I am in complete agreement with those who desire to see the school curriculum greatly lightened as regards number of subjects and wish to see 'snippets of many subjects' replaced by more thorough training in a few, my special task now is to urge the necessity of including in the training of every citizen before the completion of his school period at least a grounding in the main principles of biological science.

It is necessary in approaching any such question to keep clear in our minds the two main functions of education: (1) the educative function in the strict sense—the training and development up to the highest attainable level of the brain-power which Nature has provided, and (2) the informative function—the providing the mind with an equipment of information which will be of use to it later on.

SCIENCE AND THE CURRICULUM.

It is again necessary to glance for a moment at the general question of science in relation to education. I am, of course, one of those who believe that the almost complete exclusion of science from the elementary education of the young which has persisted over a prolonged period has been a real tragedy. In the life of the ordinary active citizen, as opposed to that of the mere scholar and recluse, some of the most important faculties are those which training in science is specially adapted to develop. Such, above all, are the powers of accurate and rapid observation, and of the accurate and rapid drawing of conclusions from observation.

I do not, however, wish to press the claim of biology to an important place in the basic stage of school education, which should have to do with the early development of these powers. On the contrary, I harbour no doubt in my mind that the department of science to be used for this purpose is not biology but physical science. For the early training of the powers of observation there are two essentials: (1) that the phenomena observed should be capable of numerical expression to a high degree of accuracy, or, in other words, that they should be measurable; and (2) that a given observation should be capable of repetition over and over again under approximately the same set of conditions. Biological observation fails as regards both of these essentials. When we proceed to apply the method of measurement to something that is alive or that has once been alive, or to some form of vital activity, we find ourselves confronted not with a phenomenon of comparative simplicity, but with a complex of extreme and, in great part, unknown intricacy.

It is rather in the later stage of education—the informative stage—when the individual has already had his powers of observation and reasoning developed in the earlier stages, that biology should be called upon to play its rôle.

What is required is by no means the storing of the memory with a vast array of separate facts. It is rather that the budding citizen should be given a grasp of broad principles, as accepted by the competent authorities of the day. Such broad principles are generalisations from immense masses of detail. The probable soundness of the generalisation is intimately related to the broadness of its basis of fact. It is, of course, impracticable to place before the pupil the entire body of facts that constitute this base, and if it were possible it would be useless, for it is only a master who is able to perceive clearly the relations of superstructure to base. The object of the teacher is then not to attempt the vain task of demonstrating the truth of the general principle in the short period available: such facts as are introduced should serve merely to illustrate the particular principle and facilitate its appreciation.

I know that there are many who will criticise as unscientific and unsatisfactory such a simple manner of approach to general biological principles. They will say you cannot really instil such principles unless you make the pupil go through an elaborate course of laboratory training in dissection and microscopic observation such as we impose upon the specialist student of biology. I do not agree. My experience has been that an audience, whether of youths or of adults, of ordinary average composition such as we get in a public lecture in a big industrial city, appreciates the points and follows the argument perfectly satisfactorily without such elaborate preparation, provided always that the argument is clothed in plain, non-technical English.

BIOLOGY IN THE CURRICULUM.

The question may now be put: What exactly are the biological facts and principles that should be introduced into such a course of instruction?

(1) First, the great fact of evolution. We still see with tiresome frequency in magazine articles the statement that evolution is not a fact, but merely an unproved hypothesis. No doubt it may be said with perfect accuracy that in one sense absolute proof is unknown to science, except in relation to successive steps of an operation in pure mathematics. Taking, however, the word 'proved' as we use it in ordinary life, *e.g.* in relation to a matter inquired into by a Court of Law, then we are completely justified by the data of embryology and palæontology in stating that evolution is a definitely proved fact. The realisation that it is a fact admitted by all competent judges should be incorporated in the mental equipment of every citizen at an early stage of his training.

(2) Secondly, the broad fact of inheritance: the fact that the offspring repeat the characters of the parent—physical, mental, moral—but that this repetition is never so complete as to amount to identity as regards such characters. It is not always realised that, were the repetition actually exact and complete, it would constitute a fact that would shake our whole biological philosophy to its foundations!

The biologist habitually using the 'species' as his classificatory unit involuntarily becomes dominated by his mental picture of the ideal member of the species, conforming exactly to description, and an individual which obviously does not so conform impresses him as a departure from his ideal. He comes in this way to think of variation as being an active positive process by itself, instead of an inherent characteristic of life and of inheritance. It would not occur to him to decry the science of physiology because it does not know the ultimate nature of the phenomena of life with which it deals, but yet he will sometimes attempt to discredit our evolutionary philosophy because it is similarly without any clear idea as to the ultimate nature and cause of the variation which is the necessary accompaniment of life.

This instability of living things which finds its expression in the constantly fluctuating incompleteness of inheritance has to be driven well home—in the first place because it constitutes the raw material of evolutionary progress, and in the second place because its proper appreciation provides the citizen with his surest safeguard against the talk of those who make it their business to belittle, if not to deny, the ever-present differences in the capacities of their fellow-men.

(3) Thirdly and lastly, the fact of the struggle for existence in Nature and the consequent elimination of the less fit. To the biologist and, indeed, to any one who devotes thought to the matter, the struggle for existence and the consequent elimination of the unfit is an obvious truism, apart altogether from the question whether or not he accepts the Darwinian view of its potency as a factor causing evolutionary change; but yet among our fellow-citizens interested in sociological questions there is a very prevalent lack of appreciation of the widespread nature and the intensity of the struggle, induced in many cases by the perusal of charming descriptions of mutual aid in the animal kingdom, combined with ignorance of the fact that such mutual aid is restricted to the individauls of a community, and that it actually constitutes an important factor in rendering the community efficient in holding its own in the struggle with other communities.

When once the pupil has fully grasped the three great primary facts I have mentioned, he can profitably pass on to elementary notions of the biology of communal life. Gateways leading to these may be found by way of the fascinating phenomena presented by communities of social insects such as bees and ants and termites. Still better in some ways is the study of cell-communities, culminating in the immensely complex cell-communities that constitute the bodies of the higher animals. By whichever route, the pupil is easily led to the three great principles of communal evolution: (1) increase in the size of the community, (2) increased specialisation of its constituent individuals, (3) increased perfection of the organisation by which the constituent individuals are knit together into the communal individuality of a higher order. In some animal communities this organisation is of a material kind, the individuals being linked together by strands of living substance, in others the connexion is not material but is of the nature of social interrelationships.

When once these basic principles are clearly apprehended an approach may profitably be made to the study of human society, where the same principles are seen clearly at work—the simple nomadic group with its individuals few in number, showing scarcely any trace of specialisation, and so loosely knit together that they separate from one another under stress of circumstances, such as attack by a hostile tribe—leading up to the complex modern civilised State with its millions of inhabitants, intensely specialised for the performance of the various communal functions, and knit together by an immensely complex social organisation.

THE INTER-COMMUNAL STRUGGLE.

The appreciation of the fact that our civilised community has come about by a long process of social evolution paves the way to an appreciation of the further fact that human societies are still in process of evolution—States becoming larger and larger, the specialisation of their citizens becoming ever more pronounced, their social organisation more complicated—and that here again a great driving force is the struggle for existence, in this case an inter-communal struggle.

It is surely one of the saddest experiences a biologist can have, to live amongst men whose communal evolution has lagged behind, and to see how, unless helped in their struggle with competitors at a higher level of social evolution by some natural protective feature such as geographical isolation or immunity to local diseases, they are doomed to disappear. Innumerable examples of this are seen in the continents of the New World, where the relatively primitive communities of red men have been displaced by whites in a higher stage of communal evolution. The same process has taken place in the past, races that lagged behind in their communal evolution giving place to others more progressive.

The realisation of the importance of this inter-communal and inter-racial competition is of use indirectly as a safeguard against falling into the common error of shutting our eyes to differences—in material interests, in racial prejudices, in religious beliefs—those troublesome factors which, in actual practice, form obstacles of the most serious kind in the way of those who would find in signed agreements between different nations a sure shield against the danger of war.

The Biological Outlook.

Finally, our training, if successful in inducing in our citizen's mind what we may call the 'biological outlook,' enables him to take a fresh and an enlightening view even of that distressful subject, economics. He appreciates more fully how the customary units of the economist, pounds and dollars, are merely tokens with local values dependent on their power of purchase. In a remote spot on the earth's surface, a pile of golden coins becomes merely so much workable material out of which articles useful or ornamental may be fashioned; a bundle of scrip becomes material of possible use for kindling a fire. Their actual value bears no relation whatever to their token value in other circumstances.

Our citizen from his biological view-point looks beyond this veil of make-believe and realises that the true unit of value is the capacity of the human individual. He sees in each individual a biological capitalist. His store of capital may be small or large. It may consist of the precious bullion, intellectual power, or the humbler metal, bodily strength. The store, small or great as it was to begin with, may have been simply left like talents buried in the earth, or by education it may have been increased in amount and coined into the kind of currency, such as skill in handicraft or other form of social activity, which gives it its greatest local value in the community.

To what End?

Now the question may fairly be put: What good would come of it all were the biologist given his way, and his subject, resting on a basis of elementary physical science, accorded the place in the ordinary school curriculum that he claims for it? How might it fairly be expected to work out in practice to the advantage of the community and of the individual citizen?

To attempt to state adequately the answer to this question would exhaust the time not merely of one address but of many, and I can only indicate one or two points which the answer would include. The scientific training we are arguing for would in the first place be a potent power on the side of social stability, inasmuch as it would help to develop the scientific habit of mind with its constant distrust of the ably stated 'case.' There is no more potent defence against the plausible rhetoric of the advocate than infusion of the scientific habit of bringing verbal statements up against the touchstone of actual fact.

With recognition of the principle that the welfare and happiness of the individual citizen is by no means independent of the material prosperity of the community, proper attention would be given to biological economics. It would be recognised that the training of the individual citizen must include the scrutiny of the nature and amount of his biological capital, and the taking of appropriate measures to increase his stock and to ensure its being minted into the most suitable form of currency.

Individual scrutiny would in turn drive home the necessity of confining within as narrow limits as possible the workings of the principle of mass production in education. The application of that principle plays a great part in industry, but its introduction into the sphere of education is apt to be accompanied by forgetfulness that its success in industry is entirely conditioned by one basic factor, namely, uniformity of raw material. Without such uniformity the practice of mass production is recognised as absurd. The clearer realisation how completely wanting this uniformity is in the human raw material on which education works will serve to impress upon us all the desirability of confining mass education within the narrow limits at the commencement of the educational period when it is for practical reasons unavoidable.

The fostering of the biological element in education would do something to quicken into renewed life the primitive relationship of parent and offspring which has tended to become deadened under the influence of modern civilisation and more especially of mass education. The parent would be no longer encouraged to regard his child as merely number so-and-so in a vast number of units poured into the hopper of the educational mill. He would be encouraged to keep up his natural sense of responsibility for the welfare and interests of his offspring—the slackening of which in our present system is responsible for so much that is deplorable—and incidentally he would be stimulated to take a live interest in the education of his children, in the selection of those responsible for the ordering of that education, and in the subject of education as a whole.

This greater interest would lead the parent to a better appreciation of many things connected with education. One of those of which a deeper appreciation is greatly needed has to do with the reciprocal relations of physical and mental deportment. Passing along a city street the biologist is constantly having his attention caught by little peculiarities of attitude and movement which reveal to him the existence of peculiarities of quite another kind—stability or instability of character, mental sluggishness or alertness. He realises to the full the reciprocal relations between mind and body.

The training of the individual to the highest attainable degree of biological aptitude as a citizen involves naturally his relations to other members of the community. He must be fit not merely to play his part as an isolated individual, but also to carry out

smoothly and efficiently his communal activities. As communal evolution progresses, these latter relations become relatively more and more important. In the primitive savage phase the individual is still subject to the ruthless pressure of natural selection. His whole organisation—his bodily health and strength, the acuity of his senses, his mental alertness—is kept up to the highest pitch. As communal evolution goes on, however, the pressure of natural selection becomes modified. In one particular respect no doubt it becomes intensified, for the crowded community provides greatly increased liability to the attacks of pathogenic microbes, and consequently we find active evolution proceeding in the direction of increased immunity to such as are prevalent and dangerous.

While, however, in this particular respect evolution proceeds actively in the more advanced communities, it is not so in other respects. The individual no longer depends on his perfect bodily fitness, on the acuity of his senses, on the alertness of his mind, to survive and reproduce. As a result, as seems beyond question, the individual necessarily deteriorates with high civilisation in his all-round fitness both mental and physical, and this retrogression renders him correspondingly more and more dependent upon the community for his welfare. Emerging from this consideration, we have the conclusion that with higher and higher communal evolution, with more and more intimate dependence of the individual upon the community, we should have greater and greater attention paid in our educational system to these subjects which have to do with the citizen's relations to and duties towards the community—such as discipline, ethics, patriotism and loyalty to country and comrades, and the past history of the community and race.

The last of these, in fact, the history of our own people, is one of the subjects of the present school curriculum which the biologist would be particularly anxious to see retained, and even accorded increased importance. His natural sympathies go out to it, for his own philosophy—evolution—is but history of a larger growth. No doubt he would sometimes wish its teaching to be modified in detail: he would like to have less attention devoted to brawls and murders—on however great a scale—and to have a little space spared for the achievements of science. In my own city of Glasgow I often wonder how much the average child is taught regarding the two great events of the world's history which took place in that city—I mean, of course, James Watt's improvement of the steam engine and Joseph Lister's inauguration of antiseptic surgery.

In these flippant days there is a tendency to scoff at pompous lines regarding 'lives of great men,' and so on; but are we quite sure that our children are not greatly the losers by hearing so little in their school days regarding the dedicated lives of great heroes of science like Darwin or Lister?

In this address, which I must now draw to its close, I have touched upon some of the general considerations which naturally come to the mind of the biologist when he thinks of his subject in relation to this great and, as it has become, vitally important problem of the training of the future citizen. Some matters that at once suggest themselves I have deliberately avoided: eugenics—there are others who speak of that; sex—the whole air is abuzz with discussions on sex. The importance of every citizen being given a little elementary knowledge of the biological aspects of health and disease; the importance of the school paying more attention than it generally does to training the power of prolonged and concentrated effort upon dull bits of work; neither of these points requires any special emphasis.

There are, however, many other aspects of the problem which I refrain from developing, only because forbidden by the tyrant Time. Summing up the more important of these, I would say that the biologist would like to see a movement of our whole educational system away from the merely literary, doctrinaire, academic regions, in which it is apt to be out of touch with the reality of biological fact and practical affairs. He would like to see a far more general recognition of the fact that the primary object of education is to make the individual able rather than learned. A learned individual may be, and often is, a stupid one. And in any case the development and the training of general brain-power fits biologically into the earlier years of life in a way that is not the case with the acquirement of mere learning.

He would regard as another prime object in the training of the citizen the getting him back towards the primitive habit of thinking constantly. The primitive savage is kept constantly alert by ever-present danger. He is constantly thinking about the meaning of what he sees and hears. Civilised man, freed from the stress of savage life, gets into the habit of not thinking. His actions become automatic. He gulps down whatever is served up to him. If he were only to think he would promptly discriminate as to what is worthy of acceptance and what is not.

The biologist would like to see still another reawakening of ancient custom, namely, the more effective shackling of personal liberty in the bonds of duty towards the community. A biologically educated community, while according to the individual in his ordinary affairs the widest range of personal freedom, would take measures to prevent effectively its interference with the public welfare, whatever might be the form of this interference.

There is one other argument I would use for the biological factor in training the citizen. As social evolution progresses, the natural differences between men become more and more marked, as does also the material expression of these differences. One individual—say a Lister—is worth to the community many millions of pounds; another is worth little or nothing, or in some cases his value may be expressed by a negative quantity. Along with this increase of inequality there comes, unhappily, the deteriorating nervous balance which accentuates discontent and social friction. The biological outlook I believe to furnish a most potent aid towards the smoothing away of such social difficulties and the lubrication of the social mechanism, for it enables us to see with clear vision through the obscuring veil of superficiality that separates class from class, and shows us how our fellow-citizens beyond, in spite of their differences in manners and clothes and language, are after all, on the average, merely human beings like ourselves, fitted out with the same strengths and trammelled by the same weaknesses as our own.

Domestic Refrigeration.

THE origin of the discovery of refrigeration as a method of food preservation is lost in the mists of antiquity. The earliest record we have of the use of cold is that the Emperor Nero employed slaves to bring snow down from the mountains to cool his wines, so it is evident that the Romans appreciated the value of refrigeration as a means of enhancing the amenities of life in hot climates. Many centuries later the story is told by Sir Walter Scott that Saladin, leader of the Mohammedan armies, sent a frozen sherbet to Richard the Lion Hearted, much to the amazement of that doughty monarch. One hopes that such a good story is not legendary.

In the thirteenth century, Marco Polo is said to have brought back to Europe recipes for water and milk ices. It is not, however, until the sixteenth century that we obtain definite evidence of refrigeration being tried as a method for arresting the chemical processes which take place in animal tissue after death. The classic experiment of Francis Bacon is worthy of note. He stuffed snow into a chicken to see if the chicken would keep fresh. This experiment had tragic consequences for Bacon; for it is related that he caught his death of cold by alighting from his carriage one winter day to try the process.

From this simple experiment a gigantic industry has arisen, and, to illustrate the magnitude of the refrigeration industry at the present day, it may be remarked that Great Britain in 1924 imported chilled and frozen meat to the value of forty-seven million pounds sterling. In spite of this rapid commercial development, progress on the purely biological side has been slow, for very little is known as to the nature of the changes which take place in flesh chilled or frozen in the course of long periods of time.

We have evidence that flesh preserved by cold from prehistoric times is at least edible, for exploration has brought to light some remarkably well preserved specimens of the mammoth. One of these found at Beresorka, Siberia, was in such a state of preservation that the frozen meat was eaten by animals and men without any ill effects. It is supposed that the creature slipped into a crevasse in a glacier which may have been covered by vegetation as in the Malapina Glacier of Alaska. It is evident that the unfortunate creature met with a violent death. The hip bone and one foreleg were broken and there was grass between the teeth and even upon the tongue.

At the present time all we can definitely say is that refrigeration as a method of food preservation is the one which causes the minimum of alteration of the desirable food properties and consequently it is to be recommended in preference to the use of preservatives.

Whilst the commercial side of the cold storage industry is well developed, and stores of enormous capacity are available, little progress has been made in Great Britain in applying refrigeration for household purposes. In the United States the domestic refrigerating plant has been pushed vigorously during the past few years. It is stated that the production of household machines in the States has increased about 100 per cent. each year for many years, and that the total now amounts to something in the neighbourhood of 100,000.

Fascinating though the subject of the domestic refrigerating plant may be from an engineering point of view, when regarded from the purely utilitarian aspect, one must recognise that great practical difficulties are involved in the introduction of the mechanical refrigerator into the household. In the first place, as British climate is not one that calls for refrigeration for any lengthy periods in the year, the machine would need to be designed so as to be ready to operate after prolonged disuse. Furthermore, it should be proof against the attentions of the too enthusiastic owner and be unaffected by neglect whilst in the care of the cook.

The 'service' required for the maintenance of a group of plants may prove to be the most serious obstacle to the successful commercial development of the domestic machine. So, whilst there can be no doubt as to the benefit of refrigeration in the home, the means of attaining it needs careful consideration. A regular and cheap supply of ice, or a cold brine supply, from one large refrigerating plant adequate to the needs of a block of buildings, may be formidable rivals to the small mechanical plant of the future.

In the present article it is proposed to give a brief sketch of two of the many refrigerating plants now on the market. The designers of such plants have approached the problem with great originality of outlook, and consequently the resulting machines bear little resemblance to the large industrial installations.

In the choice of refrigerating fluid we also find great diversity; for example, ammonia, sulphur dioxide, ethyl chloride, methyl chloride, and a mixture of ethyl chloride and methyl bromide. The properties of ammonia are so well known as to need no description. Sulphur dioxide is greatly favoured for small plants, because the working pressures are lower than is the case with ammonia machines. It is also unique among refrigerants in so much that in the liquid state it has the properties of a lubricant. The serious drawback of sulphur dioxide is its affinity for water.

The high boiling point of ethyl chloride well adapts it for use in hot climates. A disadvantage is the necessity for using as lubricant glycerine, which is hygroscopic.

Methyl chloride is a gas condensing to liquid at $-23 \cdot 7^{\circ}$ C. The admixture of methyl bromide with ethyl chloride renders the mixture non-inflammable.

The primary requirement in the case of the small plant is reliability. Certain manufacturers have produced compressor type machines which are designed so that they cannot receive any adjustment in the hands of the user beyond the turning on and off of a water tap and switch, whilst others have based their designs on the assumption that, if motive power is entirely eliminated, skilled attention becomes unnecessary. It is two of the latter type, known as absorption machines, that are described in the present article; reference may be made to the *Journal of Scientific Instruments* (August 1925) and the *Proceedings of the British Cold Storage and Ice Association*, 1925, for a description of the former class.

The absorption type of refrigerating plant is very simple in principle: ammonia gas is driven off by heat from a solution of ammonia and water; the ammonia

is condensed and the liquid ammonia then allowed to boil in an evaporator, thereby producing 'cold'; the gas is absorbed in the dilute water ammonia solution, which is now cooled by water circulation. The cycle is repeated periodically.

Many attempts have been made to render the absorption machine automatic in action, and some remarkably ingenious machines have been produced. In one, known as the Keith, the boiler and evaporator are connected by steel pipes and the whole arrangement is mounted on a pivot point so as to allow it to rock. Starting from the condition when the evaporator contains a charge of ammonia and is ready to produce 'cold' by evaporation, the following is the cycle of operations:

A stud projecting from the evaporator cools and freezes water surrounding it in a small cup attached to the wall of the cool chamber. This holds the evaporator in position until all the liquid ammonia has boiled away and is absorbed by the water in the boiler now maintained cool by water circulation. When the temperature rises the ice lock is released by the melting of the boundary of the ice in the cup and, as the boiler is several pounds heavier than the evaporator, the whole unit tilts on the pivots.

This motion switches on the electric heating to the boiler and the water on to the condenser. The ammonia vapour from the boiler is condensed in this cooler and arrives as a liquid in the evaporator. After a period of about three-quarters of an hour, the charge of ammonia has been distilled over from the boiler and condensed in the evaporator. The weight of the evaporator overbalances the boiler and the machine rocks over to the position ready for a new cycle of cooling. The operation of switching over cuts off the electric supply and switches over the water so that it circulates through a coil of pipe in the boiler.

The machine has several novel features; one is a mercury seal which is so arranged that the ammonia vapour from the evaporator is passed beneath the surface of the water in the boiler during the refrigerating part of the cycle so as to produce rapid absorption.

Another feature of the machine worthy of note is the arrangement for manufacturing a supply of small blocks of ice which can be used for cooling beverages, etc. Copper studs project from the evaporator, and project at an angle of 45° into cups. When the evaporation is complete, the ice blocks thaw slightly around the sides and are freed from the cups, permitting the machine to rock. The blocks are carried up on the studs because they are at an angle and ultimately slide off into a hopper which delivers them to an ice container located on the top shelf of the refrigerator. All the cups are automatically filled with water.

Many other attempts to render the absorption machine automatic in action have been made. Recently the problem of rendering the absorption plant both automatic and continuous in operation has been studied by two Swedish inventors, Messrs. Platen and Munters. Their machine overcomes the practical difficulties encountered by Geppert, who attempted to solve the same problem in 1899, by introducing an inert gas into the system.

A diagram of the Platen-Munters machine is given in Fig. 1. The action is as follows:—When the generator (1) is heated by a heating coil projecting into the re-entrant tube (6) the ammonia dissolved in the water evaporates, rises and enters the condenser (4), where it is liquefied. Any admixture of water vapour is condensed and separated from the ammonia in a rectifier (9) and flows back into the generator. The liquefied ammonia flows down through the condenser into the upper part of the evaporator (3), where it is met by hydrogen, which is continuously transmitted from the absorber (2) through a pipe inlet (12). The liquefied ammonia thereupon flows over a number of discs (14), placed inside the evaporator, where it evaporates in, and diffuses into, the hydrogen. This evaporation and mixing goes on until the ammonia vapour has reached the partial pressure in the mixture of gases, which corresponds to the existing conditions of temperature

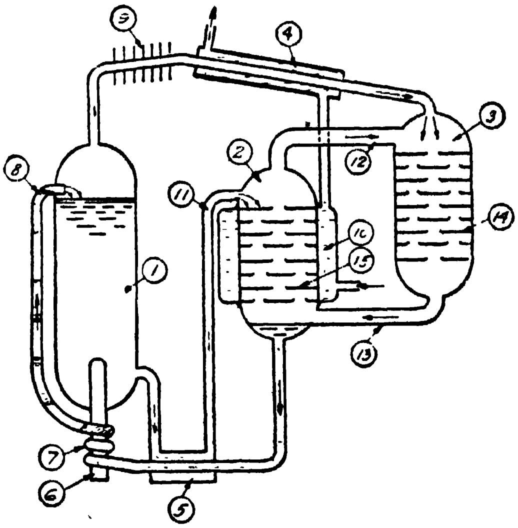

FIG. 1.—Diagram of cooling unit. 1. Generator; 2. absorber; 3. evaporator; 4. condenser; 5. heat exchanger; 6. heating medium; 7. thermo-siphon; 8. strong liquid inlet; 9. rectifier; 10. cooling jacket; 11. weak liquid inlet; 12. hydrogen inlet; 13. mixed gas outlet; 14. discs in evaporator; 15. discs in absorber. (By courtesy of Electrolux Ltd.)

and pressure in the evaporator. As the ammonia thus diffuses into the hydrogen, its partial pressure falls, but the total pressure in the evaporator remains the same as in all other parts of the apparatus. The gas mixture, consisting partly of hydrogen and partly of ammonia, is of a higher specific gravity than pure hydrogen, and therefore sinks down through the evaporator.

During the passage through the evaporator the heat-absorbing evaporation of the ammonia takes place, and accordingly heat is taken up from the surroundings through the walls of the evaporator.

From the bottom of the evaporator the gas mixture flows through a pipe (13) into the absorber (2), where it is met by a shower of water practically free of ammonia coming through a pipe (11), and passing over the discs (15) in the absorber. This water, which, by its gravity, has flowed from the generator to the absorber through the pipe (11), readily absorbs all the ammonia in the gas mixture. The hydrogen, thus denuded of ammonia, assumes thereafter the total pressure in the upper part of the absorber. The hydrogen, thus released, naturally rises, and thereby again finds its way into the evaporator. Consequently, the hydrogen rises in the absorber and sinks in the evaporator, where it

is again mixed with ammonia vapour, and in this way a continuous circulation of hydrogen between these two vessels is maintained. No hydrogen can remain in the generator while the apparatus is working, as it would be expelled by the ammonia vapour.

The return of the strong absorption liquid, from the bottom of the absorber to the generator, is provided for in a very simple way. The pipe (7-8) acts as an effective 'thermo-syphon,' by means of which the strong liquid is automatically transferred back into the upper part of the generator. The heat supplied not only lifts the liquid from the level in the absorber to the higher level in the generator, but also again releases the ammonia from the water to pursue its cycle.

It will be noticed that the weak solution when leaving the lower part of the generator is practically free from ammonia on account of the high temperature prevailing. The pipes (5) and (11), being placed inside another, act as a heat exchanger on the counterflow principle. By means of this, the hot weak liquid, which flows from the bottom of the generator into the absorber, is pre-cooled by the comparatively cold, strong liquid that flows from the absorber to the thermo-syphon. This solution is at the same time pre-heated before entering the generator.

A test was recently made at the National Physical Laboratory on behalf of Messrs. Electrolux Ltd. (153-155 Regent Street, W.1), of a small refrigerator based on the above principle. The plant supplied was built into an insulated cabinet. The generator and heat interchanger were insulated with cork. The evaporator was surrounded by a metal tank projecting into the cabinet. In the test, the evaporator tank was insulated with a layer of granulated cork. Into the tank was inserted a propeller and an electric immersion heater and thermometer. The plant was set running and the energy required in the immersion heater to maintain the tank and its contents at -5° C. was determined by trial. Then the heat abstracted by the plant under these conditions is the sum of the energy dissipated in the immersion heater and that conducted into the tank through the cork insulation. The tests were repeated at several values of the cooling water temperature.

The correction for the heat conducted into the tank was determined as follows :—After the temperature had been maintained at -5° C. for some time, the plant was switched off, and the rate of rise of temperature of the stirred liquid in the tank was observed for a considerable period. By extrapolation back of the rate of rise at various temperatures, the value of -5° C. was deduced. The heat capacity of the tank and its contents was then determined by the electrical method, the temperature rise from an initial steady temperature, due to the generation of a known quantity of heat, being measured, when the plant was not working. This, together with the rate of rise of temperature at -5° C., gives data for the rate of leakage of heat at that temperature.

The table below summarises the results.

TANK AT -5° C.

Electrical input in heating coil, 300 watts.

Inlet temperature of cooling water. (° C.)	Air temperature. (° C.)	Heat dissipated in tank around evaporator. (Kilo. cal per hr.)	Heat leakage into tank. (Kilo. cal. per hr.)	Total refrigeration effect. (Kilo cal. per hr.)
7.35	8.6	58.1	39.6	97.7
11.95	8.75	47.5	40.9	88.4
17.4	8.8	37.1	41.4	78.5

Hence it will be observed that at a cooling water temperature of 17·4° C., a total refrigeration effect of 78·5 kilo. cal. per hour is obtained for an expenditure of 258 kilo. cal. per hour in the form of electrical energy.

An ideal heat engine working between the same temperature limits and supplied with the equivalent amount of energy would give a refrigeration effect of 3090 kilo. cal. per hour.

Whether this simple ingenious machine will solve the problem of the domestic refrigerator time alone can tell. It must be realised that it is essentially an absorption type machine and, in spite of sixty years of development, this type of machine has failed to hold its own against the compressor type in the larger sized units, except where waste steam is available. An annoying trait in the older machines was the tendency for water vapour to be carried over and accumulate as ice in the evaporator.

Science in Antiquity.[1]

By Dr. J. NEWTON FRIEND.

MAN is a curious creature, at once apprehensive and superstitious. His early observations were so closely interwoven with imagination that from his records it is oft-times difficult to sift out the wheat from the chaff.

It is to Egypt that one naturally turns for the early history of science. Learning was concentrated in the temples and in the royal courts. Magicians and necromancers were intimately associated with the ruling spirits. This is well illustrated by a story in the Westcar Papyrus, concerning Seneferu, the first king of importance in the Fourth Dynasty, *circa* 3100 B.C., and the immediate predecessor of Khufu or Cheops, the builder of the Great Pyramid. It appears that upon one occasion the king was sad, and refused to be comforted by his nobles. So the magician Tchatcha-em-ankh was sent for, who advised the king to indulge in a row on the lake with a bevy of beautiful virgins. Whilst basking in the sunshine one of the maidens accidentally dropped a turquoise ornament into the water. The king, becoming acquainted with the loss, called the magician and asked him to recover

[1] Substance of a lecture delivered by the author at the Royal Institution on June 10.

the precious thing; whereupon Tchatcha-em-ankh spoke words of power, the waters of the lake heaped themselves up on one another, and the dry bed of the lake appeared with the ornament resting in the middle. This was recovered, and Tchatcha-em-ankh again spoke words of power, the waters fell back, and all was again as before. That Moses should be credited with having performed a similar miracle by making a pathway through the sea when leading the Hebrews out of Egypt need occasion no surprise. The power of a deity was measured by that of his priests, and, in the opinion of the Hebrews, Moses was no whit inferior to the followers of Amen or of Ra.

It is worthy of note that although commerce and religion demanded the use of balances in very early days, it was only about a hundred and fifty years ago that the value of the balance was generally recognised as a necessary adjunct to the systematic study of chemistry. In the Egyptian "Book of the Dead" the heart of the deceased is figured as being weighed in the Judgment Hall of Osiris, the counter-weight being truth, as typified by the ostrich feather. The balance bears an indicator, the movement of which, observed by Anubis, the Jackal-headed god of the Tomb or of embalmment, is recorded by Thoth, the Ibis-headed god, inventor of writing and science.

A similar idea of weighing good and evil runs through the Old Testament; as witness Belshazzar, who, we are told, was weighed in the balances and found wanting. It was regarded as grossly impious to use unjust weights and balances. In Hebrews ix. 4 we learn that the Ark contained Aaron's Rod, a Golden Pot, and two stones engraved with the Ten Commandments. Petrie very aptly suggests that these may have constituted the recognised Hebrew standards of length, volume, and weight respectively, which would naturally be kept under priestly control. In the Koran, written *circa* A.D. 600, the writer is evidently familiar with the conception of accurate weighing. Thus in Sura xxi. we read that "Just balances will be set up for the day of the resurrection, neither shall any soul be wronged in aught; though were a work but *the weight of a grain of mustard seed*, we would bring it forth to be weighed." About this time the Arabs appear to have had excellent balances, and some of their glass coin weights, dating back to the eighth century, have been tested in recent years and found to be remarkably accurate. Thus, three weights corresponded to 32·662, 32·665, and 32·667 grains respectively, a truly wonderful agreement (see NATURE, 1925, **115**, 963).

In A.D. 1121 an Arab, Al-Khazini by name, discussed the balance in a work entitled the "Book of the Balance of Wisdom," and gave the density of lead as 11·33. Modern values range from 11·33 to 11·35. Further, it is interesting to note that Al Jildaki, who died about A.D. 1360, stated that "substances do not react except by definite weights." A short step further and Dalton's law would have been discovered and a bridge erected over a gulf of some four hundred and fifty years.

The ancient Druids of Cæsar's time were an intelligent set of men whose schools appear to have been famous amongst the Gauls. So great was their renown that young men came over to Britain from the continent to receive instruction at first hand from them. England was the Charlottenburg of western Europe. We have too often been led to despise the Druid, who is supposed to have burned his victims wholesale in wicker cages. Even if he did, he was but in keeping with the spirit of the times. Such a death would be less lingering than crucifixion, as practised by the Romans; and certainly no more painful than the cruel Assyrian practice of flaying alive, as illustrated on their monuments.

For many reasons we may be proud of the Druids. Amongst other things they studied astronomy. To this end clocks were necessary. In the East, sun-dials were used by day and the stars by night, to tell the time; but in a climate such as that of Britain, clocks independent of the weather were a necessity. The Egyptians had two types of water-clock, but both were based on the principle that water falling into a vessel at a constant rate will uniformly raise a float, the upward movement of which is directly proportional to the time. British water-clocks, as recently shown by R. A. Smith of the British Museum, differed entirely in principle from the above, and were probably a British invention. The clock consisted of a small bronze bowl through the bottom of which a small hole was made, as in a modern flower-pot. This vessel was then floated on water in a large bronze bowl, the water slowly entering through the hole, and eventually causing it to sink. The clock appears to have been attended constantly by a slave, who would perhaps call out or strike a gong every time the vessel sank, thereby recording the time, much in the same way as the watchmen many centuries later called out the hours of the night. Vessels of bronze, somewhat resembling frying-pans, have been found in association with the bowls, and these are believed to have served as gongs for the purpose mentioned.

Alchemy may be viewed as a link between ancient and modern science. It was regarded as a divine gift, but this is not surprising when it is remembered that knowledge was mostly vested in the monasteries, and thus intimately connected with devotion. Early recipes frequently postulate that a decoction shall be heated up or otherwise treated during the recitation of a certain number of paternosters. This, of course, was to ensure that proper time was allowed for the necessary reactions to take place, and incidentally throws an interesting light on the monkish conception of time. From this it was but a short step for the superstitious to believe, or for the quack to declare, if an experiment failed, that the cause lay in lack of devotion rather than in ordinary material experimental error.

Assisting this confusion of ideas there was also a curious mystic effect due to the contact of East with West. The Eastern mind is wildly imaginative, revelling in figures of speech and parables. The more matter-of-fact Westerner, on coming into contact with Eastern science, derived, it is true, much information that was valuable, but also accepted at its face value much that was purely mystical. It was not until the time of Boyle that he was able to shake himself free from its fetters, to study Nature from a less prejudiced point of view, and thus to enter into the realm of modern science.

The British Association at Oxford.

THE history, traditions, and amenities of Oxford mark it out as a place well suited to be the scene of the annual gathering of a body like the British Association; and it may safely be pronounced that the meeting that has just come to an end is not the least successful of those that have taken place since the Association has outgrown the questionings and misgivings that accompanied its earliest activities, and has made good its claim to efficiency and usefulness in the cause of commending the results of scientific research to the consideration of the community at large. This end has been met by the more technical and specialised communications that have formed the principal business of the sections, combined with the evening discourses delivered by men eminent in their own departments of science, with public lectures in Oxford and in neighbouring towns, and with lectures specially arranged for the benefit of older scholars from the elementary schools in the city.

The fulfilment of these various purposes has been the object of much careful deliberation and contrivance during the past year, and it is the hope of those concerned in the necessary preparations that their efforts to make the present occasion a notable one have been crowned with some measure of success. Great expectations were raised by the announcement that His Royal Highness the Prince of Wales had consented to occupy the presidential chair; and it may be said at once that those expectations were amply realised. His inaugural address provided fresh evidence, if such were needed, of the interest taken in scientific progress by the highest personages in the land, and of their sense of the important bearing of a knowledge of the facts of Nature upon the welfare of the whole body of humanity. The address, admirable alike in matter and in manner, is certain, from the interesting character of its substance and the wideness of its appeal, to be of immense service in encouraging a healthy appreciation of the aims and methods of science. Nor did the good offices of the president in the same cause end with the delivery of his address. By the readiness with which he entered into the social developments of the occasion, by his accessibility, and the gracious cordiality which he showed towards all with whom he came in contact, he has done very much to promote that kindly intercourse and encourage that fellow-feeling which should affect all those who are engaged in the common task of investigating and interpreting the phenomena of Nature.

It is the opinion of many who are well qualified to judge, that the social side of these meetings, though at first sight it may seem to bear merely the appearance of a concession to the demand for amusement, has its own peculiar value in aiding that personal interchange of views and comparison of experience for which the more formal atmosphere of a scientific sitting gives often too scanty an opportunity. It is a great point gained when one scientific worker gets to know another personally. At a reception, a garden party, or on a country excursion, it very often happens that misunderstandings are removed, that causes of irritation die down, that difficulties arising from difference of temperament are smoothed over. These surely are objects worth taking some trouble to attain; nor should it be forgotten that the coming together on terms not only of scientific but also of personal sympathy may act upon the younger worker as an inspiration, and on the elder as a quickening of his interest in the new points of view that appeal to the rising generation. These ends have been well served by the Oxford meeting.

The story of St. Frideswide may be accepted as legend with some foundation in fact; and there is no reason to doubt that the schools established in connexion with her priory, the origin of which dated from the eighth century, formed the germ of the present University. Authentic history of the city begins with the raising of the castle mound by Ethelfleda, the "Lady of the Mercians," and her surrender of Oxford to her brother Edward the Elder (A.D. 912). By the end of the twelfth century Oxford was a well-known seat of learning, and before the end of the thirteenth, the noble foundation of Walter de Merton, the model of all later collegiate establishments, had started on its way. With an academic and civic history reaching back for more than a thousand years, it is perhaps strange that Oxford should have no building capable of containing more than a very moderate-sized assembly; especially when it is remembered that among the many events of historic importance that have taken place within its walls was the session of the King's parliament of 1644; this, however, was not a numerous body. But the deficiency in question was felt as a somewhat serious inconvenience when it came to be necessary to find accommodation for all those members of the Association who wished to hear the president's inaugural address, and also for those who purposed attending at the official academic and civic receptions.

The peculiarities of an ancient University, much of the life of which is embodied in colleges—all bodies with an individual constitution, in each case largely independent of that of the University—made a certain want of concentration inevitable in the space and other facilities allotted to the purposes of the meeting. A partial remedy for this inconvenience was found in the organisation of a special system of transport, by which it was possible to reach the outlying spots in the occupation of the Association without great loss of time.

It may, on the whole, be said that these and other difficulties inherent in the situation were successfully dealt with, and that the Oxford meeting of 1926 will take its place in the records of the British Association as having contributed in a remarkable degree to the maintenance and advancement of the objects of that body. A standard has been set in this and other recent annual meetings which Leeds, the seat of the next annual gathering on August 31-September 7, 1927, may be confidently expected to follow. The meeting in 1928 will be held at Glasgow.

F. A. D.

News and Views.

At all points where popular and professional opinion has ground for complaint against the present lunacy administration, the recently issued report of the Royal Commission on Lunacy affords clear and wise guidance to Parliament. The recommendations cover a wide field—public, private, and medical—and are fairly free from pettifogging and meaningless phrases. A certain vagueness appears over at least one of the more radical suggestions, namely, that concerning the end to which reorganisation of the Board of Control should be directed. But generally the advice offered is detailed and practical, or limited to the mere intimation that in particular directions improvement is desirable. The importance of provision for early treatment and for treatment without certification is generously recognised, the Commission advocating a recasting of the lunacy code "so that treatment of mental disorder should approximate as nearly to the treatment of physical ailments as is consistent with the special safeguards which are indispensable when the liberty of the subject is infringed." To this end detailed proposals are framed. The need for improving the status of asylum medical officers is expressed in terms equally explicit; so is the necessity for protecting medical practitioners, who at present undertake the duty of certification with increasing reluctance. The cost and responsibility of maintenance should, in the opinion of the Commission, be transferred from the Poor Law to the County authorities. No support is given to propagandist allegations of abuses in the administration of the Lunacy Act. On the question of the abolition or reorganisation of licensed houses, the Commission is divided. An Exchequer grant is proposed to meet the additional expenditure involved in a lunacy service such as the report envisages, and the hint is thrown out that an increase in recoveries following early care and the discovery, by research, of new possibilities of cure, will render such expenditure not wholly unremunerative. Further the Commission does not go, and it remains for its successor to present the problem of national fitness in its broader aspects as one of the major political problems of the modern State.

It is a significant fact that one of the principal founders of the British Association over which the Prince of Wales is now presiding should have belonged to his own college in Oxford, and should have preceded him at that college by almost exactly one hundred years. Dr. Charles Daubeny was up at Magdalen as a Demy from 1810 until 1814, exactly a hundred years before his successor in the presidential chair this year. This is not the time to discant upon the many-sidedness of Dr. Daubeny's work within the University. In the words of his biographer: "In his whole career Dr. Daubeny was full of that practical public spirit which delights in co-operation, and feeds upon the hope of benefiting humanity by associations of men. When the British Association came into being at York in 1831, Daubeny alone stood for the universities of England, and so standing, boldly invited that body to visit Oxford in 1832. In 1856 he became president of the Association at Cheltenham, in his native county, amidst numerous friends, who caused a medal to be struck in his honour, the only occurrence of this kind in the annals of the Association." During the recent meeting a memorial wreath was placed upon the grave of the illustrious predecessor of the present president of the Association immediately within the entrance to Magdalen College, where a simple stone inscribed "C.G.B.D." marks the place in accordance with his own wish "that he might not be separated in death from a Society with which he had been connected for the greater part of his life."

Herr Rasmussen, the Danish Minister of Defence, who is shortly paying an official visit to Denmark's colony, the Faroe Islands and her sister State, the republican kingdom of Iceland, intends thereafter to proceed to the lonely, uninhabited island of Jan Mayen, lying between Greenland, Iceland and Norway. The announced object of the Minister's visit is to arrange for the erection there of a Danish seismographic station. The Danish Government owns the buildings on the island, which were given to them, it is said, by the Austrians, who once occupied Jan Mayen. It was made the station of the Austrian polar expedition of 1882–83, but has apparently remained unclaimed ever since, though Great Britain and Norway together established a 'close season' for the seal fisheries. The whale and seal fisheries off the east and north coasts are very important during the summer. Jan Mayen land, which was discovered in 1611, by the Dutch navigator of that name, is of volcanic origin, is some 35 miles long, and practically covered with immense glaciers and, in winter, frozen waterfalls. Its highest point, an extinct volcano, is 8350 feet high. Lord Dufferin refers to the island in his book, "Letters from High Altitudes," published in 1857.

The first attempt in Great Britain to utilise the aeroplane for spraying operations in connexion with agriculture is recorded in the *Times* of August 4. Mr. George Caudwell, of Weston, near Spalding, Lincolnshire, chartered a private aeroplane piloted by Major Savage, and 40 acres of Majestic potatoes were sprayed in 25 minutes, in contrast to the two days which would have been occupied for the same operation by ordinary methods. The machine flew so low that at times it almost touched the potato tops, and the spray, in the form of a fine powder, was blown on to the leaves of the plants through two pipes on either side of the fuselage. Although this method of spraying is new to Britain, it has been applied on a large scale in the United States for the control of insect pests, extensive areas of cotton being treated in this way with considerable success. Experiments are being carried on with the view of extending the scope of application of the method to deal with a larger range of plant pests. So far as Great Britain is concerned, the report of the success of

Mr. Caudwell's initial experiment will be awaited with great interest. It would seem, however, that practical difficulties may limit the application of aerial spraying in those parts of the country which are subdivided into relatively small fields with dividing hedges, but where large open areas are available much time and labour would be economised if success is attained.

AT the recent graduation ceremonial of the University of Edinburgh an interesting address to the new graduates was delivered by Prof. J. H. Ashworth. In tracing the historical development of the Edinburgh School of Zoology, Prof. Ashworth emphasised the debt it owes to three of its professors of anatomy—Monro, Monro *secundus*, and Goodsir. The first two of these were responsible for discoveries of fundamental importance to morphological science. It was Monro who demonstrated the absence of free interchange of blood between the fœtal and the maternal parts of the placenta: it was Monro *secundus* who anticipated by eighty years the discovery by Kühne of the motor nerve-endings in muscle. The same observer, whose name is permanently registered in anatomical text-books by the 'foramen of Monro,' was also the author of the great monograph "On the structure and physiology of fishes, explained and compared with those of man and other animals." Having traced the past history of his subject, Prof. Ashworth alluded to the generous contribution of 20,000*l*. by Dr. Laurence Pullar, which, with an allocation of 18,000*l*. by the Carnegie Trust, made it at last possible to contemplate the housing of the University Department of Zoology in a building fully adequate for the special needs of zoological teaching and research. The latter part of the address was devoted to emphasising the importance of the contribution which the subject of zoology is now making to the training and outlook of the medical man on one hand, and to the general progress of mankind on the other. Zoology has established itself as an integral part in the scientific foundation of preventive medicine: it is playing a part in the advancement of civilisation and in the amelioration of the conditions of life in various parts of the world to an extent that would have been inconceivable a generation ago.

A MONUMENT to the memory of John Ericsson, the famous Swedish-American engineer, was recently unveiled at Washington, D.C., by the Crown Princess Louise of Sweden. The ceremony was under the auspices of the American Society of Swedish Engineers. Erected not far from the memorial to Lincoln, the monument consists of a group symbolic of vision, adventure, and labour, standing on a massive granite pedestal, in the front of which is a statue of Ericsson, who is depicted sitting in contemplative mood. President Coolidge, responding to the speech of the Swedish Crown Prince, remarked: "Great men are the product of a great people. They are the result of many generations of effort, toil, and discipline. They are the incarnation of the spirit of the people." An unusually precocious boy, Ericsson was born in 1803 at Filipstad, Sweden, and when quite young was employed on drawings and levelling in connexion with the Göta Canal. He resided in England from 1826 until 1839, while the rest of his life was spent in the United States. His locomotive *Novelty* competed with Stephenson's *Rocket* in 1829; he was one of the chief promoters of screw propulsion, and a pioneer in the use of hot-air engines. He is best known, however, for his design and construction of the *Monitor* turret vessel.

THE annual report of the Zoological Society of Scotland for the year ending in March last is a record of the most sucessful year in the history of the Society. The large increases in the number of visitors to the Zoological Park at Edinburgh, and in the number of new fellows admitted, witness to the growing popularity and interest in its work. During the year the new Tropical Bird House and the new Reptile House were completed, and a start has been made on the Carnegie Aquarium. The latter is being built with the aid of a grant from the Carnegie Trustees, and it is hoped to have it ready for opening at the end of the year. It will add enormously to the attractions of the gardens. In spite of the rigours of the northern winter, the stock in the gardens appears to flourish and breed in quite a satisfactory manner. The number of deaths is below the average, and a good proportion of the young animals born during the year was successfully reared. One of the most notable of the deaths was that of one of the original King penguins, which proved unable to survive the strain of incubating and rearing its last chick. The financial statement reveals a healthy condition of things, and a substantial surplus from last year's activities is to be devoted to capital purposes.

A SECOND report has been issued by the Medical Research Council on the gold treatment of tuberculosis. The drug employed was sanocrysin and the report deals almost entirely with clinical experience, based on about 140 cases treated. As a result of previous experience the dangers attending the use of the drug have been greatly lessened. There is necessarily a conflict of opinion, some clinicians believing that little benefit results from the treatment. Others, however, are very emphatic in the opinion that sanocrysin did cause unusually rapid amelioration of symptoms, particularly in the lessening of sputum and disappearance of tubercle bacilli in pulmonary tuberculosis.

THE success of the Department of the Interior of Canada in its efforts to save the buffalo from extinction is shown in the fact that the great park at Wainwright, Alberta, is unable to support a further increase in the herd at present there. This park is approximately 15 miles long and 13 miles wide, and was thought by many, even a few years ago, to be ample for all time. Provision will now have to be made for the disposal of the annual increase in the herd, and the action taken by the Department will be watched with interest.

In connexion with the recent meeting of the British Association at Oxford, the honorary degree of D.Sc. (Oxon.) was conferred upon the following distinguished visitors: Prof. Niels Bohr, professor of physics in the University of Copenhagen; The Abbé Breuil, professor of the Institute of Human Palæontology, Paris; Sir Frank W. Dyson, Astronomer Royal; Prof. A. S. Eddington, Plumian professor of astronomy in the University of Cambridge; Sir Daniel Hall, Chief Scientific Adviser to the Ministry of Agriculture; Prof. Henry Fairfield Osborn, research professor of zoology in Columbia University; Sir Edward A. Sharpey-Schafer, professor of physiology in the University of Edinburgh; Mr. F. E. Smith, Director of Scientific Research, Admiralty; Sir Josiah Stamp; Prof. Vito Volterra, professor of mathematics in the University of Rome and president of the Royal National Academy of the Lincei; Prof. Wilhelm Wien, professor of experimental physics in the University of Munich.

The Earl of Midleton will open the new buildings of the Haslemere Educational Museum, Haslemere, Surrey, on August 27 next. A memorial tablet to Sir Jonathan Hutchinson is to be unveiled by Dr. F. A. Bather on the same occasion.

Prof. Jocelyn F. Thorpe, professor of organic chemistry in the Imperial College of Science and Technology, South Kensington, has been appointed chairman of the Explosives in Mines Research Committee, in succession to Sir Frederic L. Nathan, who has resigned. Mr. F. E. Smith, Director of Scientific Research under the Admiralty, has been made an additional member of the Committee.

An autumn meeting of the Institute of Metals is to be held at Liége on September 1-4. A number of papers on the constitution and properties of non-ferrous metals and alloys will be read and discussed, and visits to works and to places of interest in the neighbourhood have been arranged. Particulars can be obtained from the secretary of the Institute at 36 Victoria Street, London, S.W.1.

The trustees of the British Museum have revived the office of secretary, which since 1851 has been combined with that of principal librarian. In future the secretary will act as assistant to the director and principal librarian, with the status of a keeper. Mr. Arundell Esdaile, hitherto assistant keeper in the Department of Printed Books, has been appointed secretary.

The Duke of York will visit the Harper Adams Agricultural College, Newport, Shropshire, on Wednesday, November 3, for the formal opening of the National Institute of Poultry Husbandry, established at the College under the joint auspices of the Ministry of Agriculture and the National Poultry Council. This signal recognition of the importance of the recent advances in the provision of adequate facilities for advanced education and experimental work in poultry husbandry will be warmly appreciated by all engaged in the industry.

An Order of Council has been issued altering the composition of the Committee of Privy Council for Medical Research, the ministerial body under which the Medical Research Council conducts its work. The Committee originally consisted of the Lord President of the Council, the Minister of Health (England and Wales), the Secretary for Scotland, and the Chief Secretary for Ireland, but the last-named office has become obsolete as a result of the changes in the government of Ireland. In view of this vacancy, and of the increasing relation of the Medical Research Council to research work in overseas parts of the Empire and in industrial medicine, the Secretaries of State for Home Affairs, for Dominion Affairs and for the Colonies have now been added to the Committee.

Dr. A. W. Hill, Director of the Royal Botanic Gardens, Kew, sailed on Saturday last for the United States, where he is attending the International Congress of Plant Sciences (the fourth International Botanical Congress) at Ithaca, N.Y., on August 16-23, as one of the official delegates of Great Britain. Dr. E. J. Butler (Imperial Bureau of Mycology), Dr. A. B. Rendle and Mr. J. Ramsbottom (British Museum (Natural History)) and Mr. Sprague (Kew) are also attending the Congress in an official capacity. After the Congress, Dr. Hill is going on to the Missouri Botanical Garden and the University of California, Berkeley, where he is to deliver three lectures, and returning via Vancouver, Toronto, Washington, D.C., and finally New York, where another lecture will be given in the Botanical Garden.

The centenary year of Lord Lister's birth will be celebrated in Edinburgh in July 1927 during the meeting of the British Medical Association. The Committee responsible for the celebration is anxious to interest students and young graduates in the significance of Lister's work, and is offering a prize of a gold medal and 25*l.* for the best essay upon the subject, "The Influence of Lister on the Evolution of Surgery." The prize is open to registered students and graduates of not more than one year's standing of any medical school of the British Empire. Essays must be submitted by May 1, 1927, to Prof. J. Fraser, Convener of the Lister Memorial Committee, 32 Moray Place, Edinburgh. The award of the prize will be made at the Lister Celebration meeting, July 1927.

The report of the sixth International Congress of Photography has been published by the Société Française de Photographie, 51 rue de Clichy, Paris (9^e^). It contains an account of the proceedings at each meeting, and the papers and reports that were presented to the Congress, but the final resolutions as to standard methods of sensitometry, and procedure in other matters in which uniformity is desirable, will be issued later. The subjects treated of at the Congress are classified under the following heads: Sensitometry, optics, photochemistry, history and documentary, and kinematography; in each case the

practical applications are dealt with as well as the fundamental theories. The membership of the Congress numbered about 240, and was well representative of all the centres of scientific photographic activity.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A chemist and metallurgist in the Government Assay Office in Cairo—A. G. Innes, c/o Chief Inspecting Engineer, Egyptian Government, 41 Tothill Street, S.W.1 (August 17). A lecturer in economics at the Imperial College of Tropical Agriculture, Trinidad—The Secretary of the College, 14 Trinity Square, E.C.3 (August 24). An assistant to the professor of surgery in the University of Bristol—The Registrar (August 28). An extra mural organiser at Armstrong College, Newcastle-upon-Tyne—The Registrar (August 31) Junior assistants at the National Physical Laboratory, preferably with some research or technical experience in either physics, engineering or electrical engineering—The Director, National Physical Laboratory, Teddington (September 4). An assistant lecturer in textile engineering at the Manchester Municipal College of Technology—The Registrar (September 20). An assistant secretary of the Oxford University Appointments Committee—The Secretary, 40 Broad Street, Oxford (October 1). A full-time assistant, or two part-time assistants, in the Department of History and Method of Science of University College, London—The Secretary, University College, Gower Street, W.C.1. Evening teachers in electrical engineering and mechanical engineering at the Croydon Polytechnic—The Principal, Central Polytechnic, Scarbrook Road, Croydon. Full-time teachers in the Physics and Chemistry Departments of the Northern Polytechnic—The Clerk to the Governors, Northern Polytechnic, Holloway, N.7.—A junior assistant under the directorate of Metallurgical Research, Research Department, Woolwich, for work mainly in connexion with technical records, reports and literature—The Chief Superintendent, Research Department, Woolwich, S.E.18.

Our Astronomical Column.

FINLAY'S COMET.—This periodic comet was discovered by Mr. Finlay, Chief Assistant at the Cape Observatory, in 1886, and was observed again in 1893, 1906, 1919. S. Kanda and S Hasunuma, of Tokyo Observatory, calculated from the 1919 observations the conditions of the present return, the perturbations by Jupiter in the interim having been considerable, producing an increase of about 6 weeks in the period. With the aid of their ephemeris, Dr. J. Stobbe succeeded in photographing the comet on August 3 at Bergedorf Observatory, near Hamburg. Its magnitude was 11·5, and its position at $0^h\ 40{\cdot}6^m$ U T. was R A $4^h\ 3^m\ 48^s$, N. Decl. 17° 48′. The position indicates that perihelion occurred Aug. 7·9 U T., which is 0·7 day later than the Tokyo prediction.

The following ephemeris is for 0^h U T.

		R.A.	N. Decl
Aug	15	$4^h\ 56{\cdot}3^m$	20° 33′
	19	5 12·8	21 14
	23.	5 28·6	21 47
	27.	5 43·9	22 13
	31.	5 58 8	22 32

The comet is a morning object passing near ζ Tauri on August 23, and entering Gemini on August 31. It is well placed for observation, but is growing slowly fainter, since the distance from both sun and earth is increasing.

A plate was exposed by Mr F. J Hargreaves of Kingswood, Surrey, on July 21 at $1^h\ 53{\cdot}5^m$ U T. At first the comet was not detected upon it, but with the guidance of Dr. Stobbe's position, Mr. P J Melotte found a faint impression of the comet in R.A. $3^h\ 2^m\ 30{\cdot}8^s$, N. Decl. 13° 19′ 36″ (Equinox 1926·0).

THE NEW SOLAR RADIATION STATION IN SOUTH AFRICA.—A bulletin issued by the Smithsonian Institution describes Dr. C. G. Abbot's journey of 30,000 miles in search of the most suitable station in the eastern hemisphere. The desiderata were an elevated region, dry clear air, reasonable accessibility, and absence of wild tribes. This last consideration caused the rejection of Khojak Peak, 70 miles northwest of Quetta, though the sky conditions were superb. Stations in the Sahara, Egypt, and Mt. Sinai were visited and rejected. His choice fell on Mt Brukkaros in South-West Africa, 200 miles south of Windhoek, and 20 miles from the railway. It is an isolated peak 5200 feet above the sea, and 2000 feet above the surrounding plain. The sky was found to be remarkably clear, the stars being brilliant right down to the horizon The rainfall is very small, none having fallen for ten months. There is a crater at the top with a gap to the south east, which was found to be suitable for the excavation of a tunnel for the bolometer. The sun will be observable an hour after sunrise. A neighbouring cave will be converted into a residence for the observers, Mr. W. H. Hoover and Mr. F A Greeley.

Mr. A. Dryden, Public Works Inspector, S W Africa, has undertaken the preparation of the building, and it is hoped to commence observations in September. There are prospects of daily observations for ten months in the year, and for three-quarters of the days in the remaining two months (the so-called rainy season). The Observatory is to supplement, not to replace, the stations already existing in Chile and California.

PROPER MOTIONS OF SOUTHERN STARS.—*Memoirs of the Royal Astronomical Society*, vol. 64 (part 2), contains a catalogue of proper motions in declination of 1738 southern stars by Dr. J. E. de Vos van Steenwijk. The recent observations of the stars were made by himself at La Plata They are compared with older observations made at the Cape, Parramatta, Santiago, Madras, and other southern observatories. The systematic corrections given by Boss have been applied. The magnitudes range from $5{\cdot}8^m$ to $8{\cdot}8^m$. The probable errors of annual motion are given, they are mainly in the neighbourhood of 0·006″.

The following seven large motions are believed to be new: No. 166, mag. 6·1, type F8, P.M. + 0·245″; No. 200, mag 6·4, type G0, P.M. + 0·457″; No. 470, mag. 6·9, type F8, P.M. + 0·713″; No. 631, mag. 7·4, type F8, P.M. + 0·593″; No. 1529, mag. 7·9, type B3, P.M. − 0·370″; No. 1774, mag. 7·0, type K0, P.M. 0·814″; No. 2664, mag. 7·2, type B8, P.M. − 0·490″. It is unfortunate that the motions in R.A. are not given.

THE PSYCHOLOGY OF AMUSEMENTS.—In the *Nineteenth Century* (July 1926) M. Willson Disher discusses the 'Psychology of the Show.' He points out the antiquity of the show or circus, a form of entertainment referred to in Homer, and its almost universal appeal. He finds that the various incidents resolve themselves into means whereby the visitor can experience novel sensations, or normal sensations in an intenser form, and so obtain a heightened thrill. Normal behaviour is overturned, people delight in seeing men, beasts, and things put to any but their ordinary uses, and they prefer to be deceived. The means employed vary with the advance of knowledge, but the experiences aimed at remain the same. The power moving the roundabout may change, but the general appearance has changed but little. Men on holiday bent prefer to be able to return to the attitude of childhood, and this can best be secured by similarity of outward appearance. Hence attempts to 'show up' the tricks of the show have but little effect on the show. People are seeking, not an appeal to their reason, but an appeal to their primary emotions, and are not grateful to those who would deprive the stimulus of its power. Perhaps Prof. Karl Groos' famous theory of play may be suitably recalled in this connexion After his theory of the play of children and animals, which suggests that, biologically, in play, instincts are exercised for later use, he urges that in adult play we seek (i.) 'completion of life,' *i.e.* to experience sensations and emotions which normally in our work receive little or no gratification, (ii.) freedom from the constraint of 'must.' Fear in a limited degree, which we invoke by our own will, is very different from the fear which we experience in defiance of our will. This the show can do for us: we need not go, we can depart when we like. There is, therefore, for a short space of time, granted to us the power to feel masters of ourselves.

CRANIOMETRY OF SINGAPORE COOLIES.—Dr. Gordon Harrower of Singapore has contributed to Vol. 54, Pt. 3, of the *Trans. Roy. Soc. Edinburgh* the results of an examination of the skulls of 54 male Tamils and 36 male Hokien obtained from unclaimed bodies of coolies. In cranial capacity the Hokien is on a par with the most intellectual races, and cannot be regarded as falling within the mesocephalic group in which Chinese skulls are generally classed. The Tamil, however, is on the border line of the meso- and microcephalic groups, approaching the modern negro. Yet the Hokien and Tamil skulls are approximately equal in length, the difference coming out in the breadth. In the different races compared, the Tamil is the second lowest, being only 0·9 mm. more than the Australian, while the maximum breadth of the Hokien is exceeded only by certain of the Burmese and the Ainu groups. The skull is markedly mesaticephalic. According to the view of Chinese ethnological history now generally held, the Hokien, who are natives of the Province of Fu-kien, are survivors of the aborigines who were driven into the highlands when the early invaders of northern China from eastern Turkestan had penetrated to the south of the Yangtze-kiang. The result of the present investigation strongly supports this view. The Hokien are a pure type, brachycephalic with high cranial capacity, narrow frontal region, well-marked prognathism, and distinctly sinotic megaseme orbits. The palate is primitive. In the Tamil skull the most noteworthy feature is the position of the foramen magnum, which is relatively far back. It appears to be a pure type characteristic of the Dravidian, and shows no element incompatible with the current view of the ethnological history of southern India.

DECCAN VILLAGE LIFE IN THE EIGHTEENTH CENTURY.—Interesting side-lights are thrown on the customs of the Marâṭhâs by selections from the diary of the Râja of Satâra, Sivâji II. or Shâhu, who reigned 1708–1749, which are quoted by Mr. S. M. Edwardes in the *Indian Antiquary* for June. The position of *pâṭel*, or headman of the village community, is shown to entail both responsibilities and privileges of no little importance. He took precedence in various functions, such as the presentation of the ritual cake at the *Holi*, the annual procession in honour of Gaṇesa and Gauri, at the annual *Poḷa* procession, when the *Poḷa*, a bull dedicated to the gods, was marked with a trident and discus and allowed to roam at large. He held a prior claim to the decoration of his house with festoons of flowers by the Mâng and with red-ochre by the Mahâr, and to the supply of water by the village Koḷi or hereditary village servant, who was the recognised water-carrier. One of the processions in which the headman claimed precedence was the annual Śirâḷśet procession, Śirâḷśet being a legendary corn-chandler who became king for a short time, and an earthen image of whom was worshipped, carried in procession, and then thrown into a well or tank An important rôle was filled by the headman in disputes about village boundaries. In a dispute of this nature in 1744, when other evidence failed to establish the facts, the *pâṭel* was ordered to put a cowhide over his head and shoulders and, so adorned, to walk step by step over the real boundaries of the village. He was then kept under watch for fifteen nights As nothing untoward happened to him he was declared to have indicated the boundary truthfully The underlying idea was that the *pâṭel*, having put the hide over his head and shoulders, became imbued with the divine influence of the sacred animal and must therefore speak the truth. In Mysore, in similar circumstances, an inferior village servant of the Holeya tribe had to carry on his head a ball of earth, scooped up in the village, with water in the middle, in which was the divine presence of the village goddess. If he went beyond the true boundary this ball of earth, it was believed, would fall to pieces, and he, having incurred the wrath of the goddess, would die in a fortnight and his house become a ruin

A NEW ISOPOD FROM THE CHATHAM ISLANDS.—Prof. C. Chilton (*Records Canterbury Mus.*, New Zealand, vol. 11, pp 321–326, 1925) has found among the Isopoda collected at the Chatham Islands five small specimens from a fresh-water stream, for which he establishes a new genus Paravireia in the subfamily Sphæromimæ. The body is very convex and capable of rolling into a ball, but this genus differs from all other members of the subfamily in having five separate segments in the abdomen. A detailed description is given of a male specimen. The group (Monolistrini) to which this new genus belongs is probably an ancient one that has survived owing to the adoption of a fresh-water, and, in most cases, an underground, mode of life. The author directs attention to the interest attaching to the occurrence of this new genus in the Chatham Islands and the genus Vireia in underground waters in Europe—two very nearly related forms in localities so remote from each other.

VITALISM AND MECHANISM.—The editor of *Scientia* returns in the issues of his review for April and May

practical applications are dealt with as well as the fundamental theories. The membership of the Congress numbered about 240, and was well representative of all the centres of scientific photographic activity.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A chemist and metallurgist in the Government Assay Office in Cairo—A. G. Innes, c/o Chief Inspecting Engineer, Egyptian Government, 41 Tothill Street, S.W.1 (August 17). A lecturer in economics at the Imperial College of Tropical Agriculture, Trinidad—The Secretary of the College, 14 Trinity Square, E.C.3 (August 24). An assistant to the professor of surgery in the University of Bristol—The Registrar (August 28). An extra mural organiser at Armstrong College, Newcastle-upon-Tyne—The Registrar (August 31). Junior assistants at the National Physical Laboratory, preferably with some research or technical experience in either physics, engineering or electrical engineering—The Director, National Physical Laboratory, Teddington (September 4). An assistant lecturer in textile engineering at the Manchester Municipal College of Technology—The Registrar (September 20). An assistant secretary of the Oxford University Appointments Committee—The Secretary, 40 Broad Street, Oxford (October 1). A full-time assistant, or two part-time assistants, in the Department of History and Method of Science of University College, London—The Secretary, University College, Gower Street, W.C.1. Evening teachers in electrical engineering and mechanical engineering at the Croydon Polytechnic—The Principal, Central Polytechnic, Scarbrook Road, Croydon. Full-time teachers in the Physics and Chemistry Departments of the Northern Polytechnic—The Clerk to the Governors, Northern Polytechnic, Holloway, N.7.—A junior assistant under the directorate of Metallurgical Research, Research Department, Woolwich, for work mainly in connexion with technical records, reports and literature—The Chief Superintendent, Research Department, Woolwich, S.E.18.

FINLAY'S COMET.—This periodic comet was discovered by Mr. Finlay, Chief Assistant at the Cape Observatory, in 1886, and was observed again in 1893, 1906, 1919. S. Kanda and S. Hasunuma, of Tokyo Observatory, calculated from the 1919 observations the conditions of the present return, the perturbations by Jupiter in the interim having been considerable, producing an increase of about 6 weeks in the period. With the aid of their ephemeris, Dr. J. Stobbe succeeded in photographing the comet on August 3 at Bergedorf Observatory, near Hamburg. Its magnitude was 11·5, and its position at $0^h\ 40{\cdot}6^m$ U.T. was R.A. $4^h\ 3^m\ 48^s$, N. Decl. 17° 48′. The position indicates that perihelion occurred Aug. 7·0 U.T., which is 0·7 day later than the Tokyo prediction.

The following ephemeris is for 0^h U.T.

	R.A.	N. Decl.
Aug 15.	$4^h\ 56{\cdot}3^m$	20° 33′
19	5 12·8	21 14
23.	5 28·6	21 17
27.	5 43·9	22 13
31.	5 58·8	22 32

The comet is a morning object passing near ζ Tauri on August 23, and entering Gemini on August 31. It is well placed for observation, but is growing slowly fainter, since the distance from both sun and earth is increasing.

A plate was exposed by Mr. F. J. Hargreaves of Kingswood, Surrey, on July 21 at $1^h\ 53{\cdot}5^m$ U.T. At first the comet was not detected upon it, but with the guidance of Dr. Stobbe's position, Mr. P. J. Melotte found a faint impression of the comet in R.A. $3^h\ 2^m\ 30{\cdot}8^s$, N. Decl. 13° 19′ 36″ (Equinox 1926·0).

THE NEW SOLAR RADIATION STATION IN SOUTH AFRICA.—A bulletin issued by the Smithsonian Institution describes Dr. C. G. Abbot's journey of 30,000 miles in search of the most suitable station in the eastern hemisphere. The desiderata were an elevated region, dry clear air, reasonable accessibility, and absence of wild tribes. This last consideration caused the rejection of Khojak Peak, 70 miles north-west of Quetta, though the sky conditions were superb. Stations in the Sahara, Egypt, and Mt. Sinai were visited and rejected. His choice fell on Mt. Brukkaros in South-West Africa, 200 miles south of Windhoek, and 20 miles from the railway. It is an isolated peak 5200 feet above the sea, and 2000 feet above the surrounding plain. The sky was found to be remarkably clear, the stars being brilliant right down to the horizon. The rainfall is very small, none having fallen for ten months. There is a crater at the top with a gap to the south-east, which was found to be suitable for the excavation of a tunnel for the bolometer. The sun will be observable an hour after sunrise. A neighbouring cave will be converted into a residence for the observers, Mr. W. H. Hoover and Mr. F. A. Greeley.

Mr. A. Dryden, Public Works Inspector, S.W. Africa, has undertaken the preparation of the building, and it is hoped to commence observations in September. There are prospects of daily observations for ten months in the year, and for three-quarters of the days in the remaining two months (the so-called rainy season). The Observatory is to supplement, not to replace, the stations already existing in Chile and California.

PROPER MOTIONS OF SOUTHERN STARS.—*Memoirs of the Royal Astronomical Society*, vol. 64 (part 2), contains a catalogue of proper motions in declination of 1738 southern stars by Dr. J. E. de Vos van Steenwijk. The recent observations of the stars were made by himself at La Plata. They are compared with older observations made at the Cape, Parramatta, Santiago, Madras, and other southern observatories. The systematic corrections given by Boss have been applied. The magnitudes range from $5{\cdot}8^m$ to $8{\cdot}8^m$. The probable errors of annual motion are given; they are mainly in the neighbourhood of 0·006″.

The following seven large motions are believed to be new: No. 166, mag. 6·1, type F8, P.M. + 0·245″; No. 200, mag. 6·4, type G0, P.M. + 0·457″; No. 470, mag. 6·9, type F8, P.M. + 0·713″; No. 631, mag. 7·4, type F8, P.M. + 0·593″; No. 1529, mag. 7·9, type B3, P.M. − 0·370″; No. 1774, mag. 7·0, type K0, P.M. − 0·814″; No. 2664, mag. 7·2, type B8, P.M. − 0·490″. It is unfortunate that the motions in R.A. are not given.

THE PSYCHOLOGY OF AMUSEMENTS.—In the *Nineteenth Century* (July 1926) M. Willson Disher discusses the 'Psychology of the Show.' He points out the antiquity of the show or circus, a form of entertainment referred to in Homer, and its almost universal appeal. He finds that the various incidents resolve themselves into means whereby the visitor can experience novel sensations, or normal sensations in an intenser form, and so obtain a heightened thrill. Normal behaviour is overturned, people delight in seeing men, beasts, and things put to any but their ordinary uses, and they prefer to be deceived. The means employed vary with the advance of knowledge, but the experiences aimed at remain the same. The power moving the roundabout may change, but the general appearance has changed but little. Men on holiday bent prefer to be able to return to the attitude of childhood, and this can best be secured by similarity of outward appearance. Hence attempts to 'show up' the tricks of the show have but little effect on the show. People are seeking, not an appeal to their reason, but an appeal to their primary emotions, and are not grateful to those who would deprive the stimulus of its power. Perhaps Prof. Karl Groos' famous theory of play may be suitably recalled in this connexion After his theory of the play of children and animals, which suggests that, biologically, in play, instincts are exercised for later use, he urges that in adult play we seek (i.) 'completion of life,' *i.e.* to experience sensations and emotions which normally in our work receive little or no gratification, (ii.) freedom from the constraint of 'must.' Fear in a limited degree, which we invoke by our own will, is very different from the fear which we experience in defiance of our will. This the show can do for us: we need not go, we can depart when we like. There is, therefore, for a short space of time, granted to us the power to feel masters of ourselves.

CRANIOMETRY OF SINGAPORE COOLIES.—Dr. Gordon Harrower of Singapore has contributed to Vol. 54, Pt. 3, of the *Trans Roy. Soc. Edinburgh* the results of an examination of the skulls of 54 male Tamils and 36 male Hokien obtained from unclaimed bodies of coolies. In cranial capacity the Hokien is on a par with the most intellectual races, and cannot be regarded as falling within the mesocephalic group in which Chinese skulls are generally classed. The Tamil, however, is on the border line of the meso- and microcephalic groups, approaching the modern negro. Yet the Hokien and Tamil skulls are approximately equal in length, the difference coming out in the breadth. In the different races compared, the Tamil is the second lowest, being only 0·9 mm. more than the Australian, while the maximum breadth of the Hokien is exceeded only by certain of the Burmese and the Ainu groups. The skull is markedly mesaticephalic. According to the view of Chinese ethnological history now generally held, the Hokien, who are natives of the Province of Fu-kien, are survivors of the aborigines who were driven into the highlands when the early invaders of northern China from eastern Turkestan had penetrated to the south of the Yangtze-kiang. The result of the present investigation strongly supports this view. The Hokien are a pure type, brachycephalic with high cranial capacity, narrow frontal region, well-marked prognathism, and distinctly sinotic megaseme orbits. The palate is primitive. In the Tamil skull the most noteworthy feature is the position of the foramen magnum, which is relatively far back. It appears to be a pure type characteristic of the Dravidian, and shows no element incompatible with the current view of the ethnological history of southern India.

DECCAN VILLAGE LIFE IN THE EIGHTEENTH CENTURY.—Interesting side-lights are thrown on the customs of the Marâṭhâs by selections from the diary of the Râja of Satâra, Sivâji II. or Shâhu, who reigned 1708–1749, which are quoted by Mr. S. M. Edwardes in the *Indian Antiquary* for June. The position of *pâṭel*, or headman of the village community, is shown to entail both responsibilities and privileges of no little importance. He took precedence in various functions, such as the presentation of the ritual cake at the *Holi*, the annual procession in honour of Gaṇésa and Gauri, at the annual *Poḷa* procession, when the *Poḷa*, a bull dedicated to the gods, was marked with a trident and discus and allowed to roam at large. He held a prior claim to the decoration of his house with festoons of flowers by the Mâng and with red-ochre by the Mahâr, and to the supply of water by the village Koḷî or hereditary village servant, who was the recognised water-carrier. One of the processions in which the headman claimed precedence was the annual Śirâḷśet procession, Śirâḷśet being a legendary corn-chandler who became king for a short time, and an earthen image of whom was worshipped, carried in procession, and then thrown into a well or tank. An important rôle was filled by the headman in disputes about village boundaries In a dispute of this nature in 1744, when other evidence failed to establish the facts, the *pâṭel* was ordered to put a cowhide over his head and shoulders and, so adorned, to walk step by step over the real boundaries of the village. He was then kept under watch for fifteen nights. As nothing untoward happened to him he was declared to have indicated the boundary truthfully The underlying idea was that the *pâṭel*, having put the hide over his head and shoulders, became imbued with the divine influence of the sacred animal and must therefore speak the truth. In Mysore, in similar circumstances, an inferior village servant of the Holeya tribe had to carry on his head a ball of earth, scooped up in the village, with water in the middle, in which was the divine presence of the village goddess. If he went beyond the true boundary this ball of earth, it was believed, would fall to pieces, and he, having incurred the wrath of the goddess, would die in a fortnight and his house become a ruin.

A NEW ISOPOD FROM THE CHATHAM ISLANDS.—Prof. C. Chilton (*Records Canterbury Mus.*, New Zealand, vol. 11, pp. 321-326, 1925) has found among the Isopoda collected at the Chatham Islands five small specimens from a fresh-water stream, for which he establishes a new genus Paravireia in the subfamily Sphæromínæ. The body is very convex and capable of rolling into a ball, but this genus differs from all other members of the subfamily in having five separate segments in the abdomen. A detailed description is given of a male specimen. The group (Monolistrini) to which this new genus belongs is probably an ancient one that has survived owing to the adoption of a fresh-water, and, in most cases, an underground, mode of life. The author directs attention to the interest attaching to the occurrence of this new genus in the Chatham Islands and the genus Vireia in underground waters in Europe—two very nearly related forms in localities so remote from each other.

VITALISM AND MECHANISM.—The editor of *Scientia* returns in the issues of his review for April and May

to the consideration of vitalism and mechanism, and seeks a solution of an intermediate character. In the June issue M. Leclerc du Sablon briefly examines the principal criteria which serve to distinguish living matter, and points out that in essence they are the transformations of matter and of energy which take place in the protoplasm of living beings. He believes that it is permissible to hope that the progress of chemical knowledge, which has already elucidated so many matters which appeared to our intelligence mysterious and inaccessible, may one day reveal to us the mechanism of life. He holds that it is a purely verbal solution to attribute the activity of living matter to a vital force. Every progressive step has permitted a deeper penetration into the knowledge of the phenomena which characterise life, and it is only by the slow and empirical method—as in the case of physics and chemistry—that our ideas of living matter can become more clear and more adequate. No other way can be adopted without going outside the prescribed limits of science. He concludes that the nature and origin of life may serve as a theme for the speculation of philosophers; they are not subjects of study for biologists.

THE CONTROL OF LOBSTER FISHERIES.—The interim report recently issued of the Interdepartmental Committee appointed by the Minister of Agriculture and Fisheries and the Secretary for Scotland to inquire into the crab and lobster fisheries of Great Britain (London: H.M. Stationery Office, 1926. 2s. 6*d*. net) gives the results of the Committee's inquiry into the lobster fishery only, the crab fishery being left until further evidence, which is to be obtained, has been considered. In accordance with the terms of reference, the Committee deals at some length with the question of further protection of the lobster of both sexes by an increase in the size below which the animal may not be taken, and of the berried female by forbidding its landing and exposure for sale during the whole or parts of the year, and the opinion is expressed that a real protection of the berried lobster would materially help to maintain an adequate lobster population. At the same time, it is held that the present position of the lobster fishery and such statistics as are available do not warrant immediate legislation in this direction In a minority report Prof. A. Meek gives statistical evidence, accumulated since 1905 by the Northumberland Sea Fisheries Committee, which he regards as adequate grounds for the framing of an act to protect the berried lobster. An undersized lobster is of little commercial value, and, so far as the writer's experience goes, there is but little contravention of the law forbidding its landing and sale; but fishermen strongly resent, as an interference with their calling, the imposition of a penalty for the landing and sale of a berried lobster. The Committee feels that the experiments which are being made in various countries in the artificial hatching of lobsters should be closely followed.

PARASITIC FUNGI IN BRITAIN.—The latest report on the occurrence of fungus, bacterial and allied diseases of crops in England and Wales, covers the three years 1922–1924 (G. H. Pethybridge, *Miscellaneous Publications* No. 52, Ministry of Agriculture and Fisheries). More diseases are listed than in the previous report, chiefly because additional host plants have now been admitted, these being mostly pasture and horticultural crops. Diseases which are new to the survey and in some cases new to Britain are indicated, and special reference is made to the downy mildew of the hop, *Pseudoperonospora Humuli* (Miy. and Tak.) Wilson, first noticed in Great Britain in 1920, which is now considered to be a probable native species which, up to the present, has been overlooked. Attention is also directed to the discovery that apple and pear scab are able to overwinter on dead fallen leaves and to produce on them their ascigerous stages which serve as centres for early spring infection. The concluding index of parasitic diseases is intended to provide as clear an idea as possible of the number and nature of the parasites associated with the crops dealt with in this survey, as a contribution towards a more complete list of British parasitic fungi than at present exists.

PENETRATION OF LIGHT INTO THE SEA.—The second number of the *Journal du Conseil International pour l'Exploration de la Mer*, published in May at Copenhagen under the editorship of Dr. E. S. Russell, continues the high standard of the first number, which was reveiwed in NATURE of May 22. In a paper by Dr. W. R. G. Atkins, researches are described dealing with the penetration of light into the sea and the increase in the coefficient of absorption on approaching land, owing to the presence of more particles in suspension. Since plant growth is dependent upon an adequate supply of light for the endothermic process of converting carbon dioxide into carbohydrates, the depth of the layer which is adequately illuminated is a major factor controlling the abundant flora of minute plants suspended in the water which the sea supports. As on land, the fauna are ultimately dependent upon the flora for their food supply, so a consideration of the conditions of plant growth in the sea is of fundamental importance for any inquiry concerning the fertility of particular areas of the ocean. The author also discusses the importance of the thermal stratification of the water, which restrains the mixing of bottom water, where the necessary phosphates and nitrates are regenerated from dead organisms, with the upper illuminated layers. An interesting point which has evolved is that a white disc let down into the sea is no longer visible from above after it reaches a depth at which the intensity of light is approximately one third of that in air at the surface.

AGES OF RADIOACTIVE MINERALS FROM AUSTRALIA.—The *American Journal of Science* for July contains a very interesting record of the analyses of Australian radioactive minerals compiled by Prof. L. A. Cotton. Unfortunately the lead-ratios are not given, and the ages are calculated from the formula $8000 \cdot Pb/(U + 0 \cdot 384\ Th)$ million years. The best modern data suggest that the factor 8000 should be about 6600. Making this correction, the pre-Cambrian mackintoshite and thorogummite from Wodgina are calculated to be about 1200 million years old. This result is probably a little high, for altered uranium minerals generally tend to lose more uranium than lead, proportionately. It agrees fairly well, nevertheless, with the ages of other minerals from the early Proterozoic era. The monazite from Normanville is also pre-Cambrian and gives a (corrected) age of 930 million years, a figure that agrees closely with the ages of permatitic minerals from Scandinavia, India, Ontario, and other localities. Results are given for other minerals, but as these are recognised to be altered, their evidence is not of immediate value for either age determinations or correlative purposes.

DUST IN MINES.—The Safety in Mines Research Board has issued its fourth annual report showing the researches in progress and the numerous subjects that are being dealt with, and including the report for 1925 of the Health Advisory Committee (London: H.M. Stationery Office, 1926. 1*s*. net). So far only

one research appears to have been completed, and a separate pamphlet, Paper No. 23 (Mines Department: Safety in Mines Research Board. Paper No. 23: A Method of Trapping the Dust produced by Pneumatic Rock Drills. By P. S. Hay. London: H.M. Stationery Office, 1926. 6*d.* net), has been issued descriptive of it. It consists of an appliance for trapping the dust produced in rock drilling. As is well known, the fine dust produced in drilling siliceous rocks is a serious menace to the health of the men engaged in the work, being the source of the dangerous disease known as miners' phthisis. The invention consists of a cap placed over the hole which is being drilled, the cap being connected by a suitable flexible pipe to a filter bag, whilst the necessary suction is produced by the exhaust air from the rock drill. Experiments tried with the appliance in actual underground mining operations have been highly satisfactory, and seem to have demonstrated that the apparatus is practical and convenient, and that by its use the air within the working in which the drilling is being done can be kept free from dangerous dust particles, so preventing any risk to the health of the men engaged in the work.

THE GROWTH OF SURFACE TENSION IN SOLUTIONS OF COMMON SALT.—The growth of the surface tension in newly formed surfaces of pure water has been investigated by Messrs. Hiss, Schmidt and Steyer, and Dr. E. Kleinmann in the *Annalen der Physik*, June 2, describes measurements, using the same method, on solutions of common salt. A tube with a fine and accurately measured opening at the top dips in the liquid, which can be raised and lowered on a slide. A stream of air blown horizontally across the opening causes the liquid to rise through the same, where it is blown away in spray. The air stream can be cut off electrically by means of a contact carried on a Helmholtz pendulum, which has a second movable contact producing an electric spark to illuminate the hole shortly after the air current has been shut off. The newly formed meniscus can be observed by means of a microscope, and its behaviour shows that the increase in surface tension follows an exponential law, the full value being reached in a small fraction of a second. The differences between the behaviour of water and salt solutions are studied, and some theoretical conclusions are drawn.

ALUMINIUM ANODE FILM DIELECTRIC.—It is known that various types of electrolytic cell possess unilateral conductivity, that is, they allow the electric current to pass through them much more readily when it flows in one direction than when it flows in the other. Such a device can be used to rectify alternating current into current pulsating in one direction. When we have, for example, one electrode of aluminium and one of some other conducting substance in a bichromate solution, then, when the aluminium electrode is at the higher potential, practically no current flows through the cell, provided that the potential difference is less than a certain critical value. When the potential difference is reversed a large current flows. Devices of this nature are largely used for 'lightning' arresters in electric traction. Mr. Subramanian has published in vol. 8B of the *Journal of the Indian Institute of Science* an interesting paper on the aluminium anode film dielectric. He finds that the leakage resistance of the film formed on the aluminium electrode is inversely proportional to the applied voltage for a given formation voltage and is directly proportional to the formation voltage. This resistance also is nearly independent of the frequency. The film when subjected to a voltage exceeding the critical value collapses, the breakdown being accompanied by flashes of light and crackling sounds, the pitch of which appears to be an octave higher than the frequency of the supply voltage. The electrostatic capacity of the double film in ammonium borate increases slowly with the time.

THE SYNTHESIS OF NITROUS OXIDE.—The first direct synthesis of nitrous oxide has been carried out by a method due to D. L. Chapman, R. A. Goodman and R. T. Shepherd, which is described in the *Journal of the Chemical Society* for June 1926. The gas is obtained when nitrogen at low pressures is submitted to an electric discharge in a quartz tube, the walls of which have been impregnated with oxygen by means of the discharge. The gas is analysed by heating a platinum wire in it, when the volume increases in the ratio of 2 to 3. When the decomposition products are exploded with hydrogen, it is found that the proportion of nitrogen to oxygen is 2 to 1, leaving no doubt that the gas is nitrous oxide.

DETONATION TEMPERATURES IN CLOSED VESSEL EXPLOSIONS.—No. 1005 (E. 17) of the Reports and Memoranda of the Aeronautical Research Committee (Note on 'Detonation' Temperatures in Closed Vessel Explosions, by R. W. Fenning. I.C.E. 519. London: H.M. Stationery Office, 1926. 6*d.* net) supplements a former report on the temperature and pressure of the unburnt residue of the charge at the start of detonation in closed vessel explosions. The records of the experiments performed by R. W. Fenning make it quite clear that the chief factor in the production of explosions in mixtures of air with petrol, hexane, pentane or heptane is the temperature, the pressure having little or no effect.

THE PHOTOCHEMICAL DECOMPOSITION OF SILVER IODIDE.—The microbalance has been used by E. J. Hartung to study the photochemical decomposition of silver iodide. Thin layers of silver, chemically deposited on vitreous silica sheets, were iodinated and the films of pure iodide exposed to sunlight in oxygen, hydrogen, and nitrogen respectively at different pressures in the presence of silver, which was used as an iodine absorbent. The results of these experiments, and those on the rate of iodination of silver and previously insolated silver iodide, are published in the *Journal of the Chemical Society* for June 1926. They show that the decomposition into silver and iodine takes place in the absence of oxygen, the maximum percentage loss of iodine being, in hydrogen 91·6 per cent., in nitrogen 88·5 per cent., and in oxygen 94 per cent.

THE SLOW OXIDATION OF PHOSPHORUS TRIOXIDE.—The product of the luminescent oxidation of phosphorus trioxide has hitherto been assumed to consist of phosphorus pentoxide. A paper published in the *Proceedings of the Royal Society of Edinburgh*, Vol. 46, part 2, No. 21, describes the work of C. C. Miller, which proves that under certain conditions the tetroxide is produced. Phosphorus trioxide in the presence of water vapour of 0·1 mm. pressure from 98 per cent. sulphuric acid was submitted to the action of oxygen at a pressure of 600 mm. and at a temperature of 25°. The light snow-like solid was shaken into a weighed tube and analysed by oxidising the water solution with potassium bromate, treating with hydrochloric acid and excess of potassium iodide, the liberated iodine being titrated with sodium thiosulphate. The total phosphorus was obtained by precipitation as magnesium pyrophosphate after the solution had been boiled with strong nitric acid to remove halogens. The analytical results were confirmed by microscopic investigation of the resublimed crystals.

The Gustatory Sensory Reflex.

We have already referred to certain of the researches carried out on the special senses by F. Allen and his collaborators in describing his investigation of the tactile sensory reflex. A recent paper on the gustatory sensory reflex presents an analysis of the sense of taste, the last of the 'five' special senses to be examined by this author, using the method which has proved so successful in the case of the senses of vision, hearing and touch; the sense of smell has so far defied investigation in this manner (F. Allen and Mollie Weinberg, *Quart. Journ. Exp. Physiol.*, 15, 385, 1925). The results obtained agree with what is known at present of the sense of taste, and, moreover, can be expressed by a formula which is closely related to those derived for the other three senses investigated.

The method used in all these researches is the determination of the fusion point of interrupted stimuli applied to the end-organ concerned. Thus in vision it is the critical frequency of flicker of the colour which is determined; in sound, the critical frequency of pulsation of the tone; and in touch, the critical frequency of percussion, by means of an interrupted blast of air; so in taste, the critical frequency of an interrupted electrical stimulus applied to the tongue is observed, using varying intensities of stimulation. The authors chose electrical stimulation of the tongue, which produces a sensation of sourness, as the most satisfying method of stimulating the taste-buds, the end-organs of taste, which are found in large numbers on the circumvallate and fungiform papillæ on the dorsal surface of the organ; their method requires the application of a stimulus of definite intensity to the same point at equal intervals of time and lasting only a definite fraction of a second. It is obvious that the mechanical application of substances in solution cannot be utilised for this purpose. In taking readings the tip of the tongue was protruded into a small mouthpiece containing the stimulating electrodes, the negative being applied to the dorsum and the positive to the under surface, so that the current ran through the tissue of the tongue itself; each measurement was completed in from two to three and a half seconds.

The results obtained, using different strengths of stimulation from 0·2 to 0·7 volt, at first sight appeared very irregular, but when plotted, with duration of the stimulus at the critical frequency as ordinate and intensity as abscissa, the readings were seen to fall along four curves, convex towards the abscissa: thus there are four fusion points for each strength of the stimulus. Since only four primary taste sensations are recognised, it was extremely probable that each of these curves represented the arousal of one of these sensations. The curve for the sour sensation was taken as the one on which the greatest number of points fell, since the actual stimulus used gave rise to this sensation. The identification of the other curves required special experiments.

It is known that gymnemic acid abolishes temporarily sweet and bitter sensations; after the application of a 0·5 per cent solution to the spot on the tongue at which the measurements were made, only two complete curves and a portion of another were obtained. None coincided with any of the normals; their position indicated depression of the receptors in the tongue. The authors considered that the incomplete curve corresponded to the bitter sensation, the receptors of which only responded to relatively strong stimulation, and that the normal curve, above which this portion lay, was the curve of bitter sensation; the remaining two curves then represented the depressed sensations of sour and salt, and assuming they were equally depressed, the normal curve for the latter could be placed; the remaining curve, unrepresented after gymnemic acid, must be that of the sweet sensation. The curves fall into the following order, commencing with the most sensitive: bitter, sour, salt, sweet; the duration of stimulation at the fusion point, using 0·2 volt as stimulus, is from 0·0015 sec. to 0·0025 sec. (bitter and sweet respectively, with sour and salt giving intermediate values). With 0·7 volt the four curves approach one another with a duration of stimulation at the critical frequency of the order of 0·005 sec. The correctness of the identification of the curves is confirmed by the fact that the receptors for the four sensations, when investigated by tasting solutions of different strengths, can be placed in the same order of relative sensitiveness.

It may be noted that the fusion point of the electrical stimuli in any given experiment cannot be predicted; in fact, it may change during its course. Since the stimulation produces a sour sensation, but at the same time affects the receptors of the other sensations, it is probable that every gustatory stimulus affects the four sets of receptors in varying degree, stimulation of one set, however, predominating.

The effects of previous stimulation of the same or opposite side of the tongue upon the position of the fusion curves were also studied. The application of a weak solution of quinine bisulphate to either side of the tongue resulted in depression of all four sensations; that is, at a given voltage, fusion of the stimuli was obtained with a longer duration of each stimulus. Acetic acid applied to the same side of the tongue depressed all sensations except sweet, but applied to the opposite side, it produced an enhancement of all sensations. A solution of 10 per cent. sodium chloride depressed the sour, and bitter, and especially the salt, sensations, after homolateral application, but enhanced the sweet. Between strengths of stimulation represented by 0·4 volt and 0·6 volt this enhancement was very marked. A 20 per cent. solution applied to the opposite side of the tongue resulted in enhancement of all four sensations. Enhancement was also caused by a 20 per cent. cane sugar solution applied to the same side as the stimuli, but with 5 per cent. solution depression of the sweet, salt and sour sensations occurred.

It is thus clear that previous stimulation of a gustatory end-organ leads to a change in sensitiveness both of itself and of neighbouring end-organs, which may be in the direction of either depression or enhancement. The authors explain these results by postulating the release of efferent impulses to the end-organs following the receipt of the afferent impulses in the central nervous system; the efferent impulses are of two kinds, causing depression and enhancement of the receptors, and according as one set prevails over the other, so is the end-organ depressed or enhanced: a weak stimulus results in depression, a strong in enhancement.

The fusion curves correspond to the equation

$$\frac{1}{D} = -K \log Q + C,$$

where $1/D$ is the reciprocal of the duration of the stimulus at the critical frequency of gustation (or fusion point), Q is the quantity of electricity, and K and C are constants. This equation is closely related to those found by the same method of experimentation for vision, hearing and touch: in vision the negative $\log Q$ is replaced by the positive logarithm of the intensity of the light stimulus; in hearing and touch, the duration of the stimulus replaces its reciprocal, and in the former the logarithm of the air pressure is

positive, in the latter negative; in these latter two, low intensities of stimulation produce enhancement, and the higher the reverse.

When the logarithmic curves are plotted it is found that they are straight lines with two abrupt changes of slope. In their previous communication, Allen and Hollenberg (*ibid.*, vol. 14, p. 351, 1924) described only two instead of three branches in the curves of the tactile sensations. Allen and Weinberg have reinvestigated this point (*ibid.*, vol. 15, p. 377, 1925), and find that the superficial pressure sense certainly conforms with the other senses in showing three branches in its logarithmic curve, and that the deep pressure sense shows a curve of similar nature, though the lowest branch is missing, probably because the apparatus used was incapable of delivering a sufficiently rapid series of air-puffs to reach the critical frequency at low air pressures. It appears, then, that the sense of pressure agrees in its general characteristics with the other three senses investigated. To obtain results with low air pressures the authors found it necessary to use a more sensitive surface than the palmar aspect of the forefinger, and so carried out their experiments on the lip.

The similarity of the results obtained in the case of the four senses of sight, touch, hearing and taste, together with the shapes of the logarithmic curves, suggests that the sensitivity of the receptive end-organs is under the control of the nervous system in each case. This sensitivity can be increased or diminished by stimulation of any of the receptors, the enhancement or depression affecting not only the receptors stimulated but also, by reflex action, the others which are at rest.

International Ornithological Congress at Copenhagen.

THE sixth International Ornithological Congress was held in Copenhagen on May 24-29, Dr. Ernst Hartert being the president. It should have taken place in Sarajevo in 1915, but, this being impossible, Copenhagen was chosen, where local ornithologists, Herr Lehn Schiöler, Prof. Wesenberg-Lund, and Mr. Bovien, the secretary, made excellent arrangements. The meetings took place in the splendid rooms of the Parliament Building (in the Christiansborg castle), kindly put at the disposal of the Congress by the Danish Government. More than 200 members were announced, but only 164 actually attended. Nearly all European countries were represented, as well as the United States of America, Argentina, Canada, Brazil, Cuba, India and Japan. Next to Denmark, Germany was by far the most strongly represented country, and 18 British members were present.

More than 50 papers had been announced of which 47 were read; time being too short to read all, those authors who were present were given preference. The lectures were divided between the general meetings and five sections: Section (1): Systematic ornithology, geographical distribution, palæontology; (2) anatomy, physiology, heredity and evolution; (3) biology, including ecology and bird-migration; (4) oology, nidification; (5) bird-protection and aviculture. These five sections were amalgamated into two or three, as there were no or only single papers on several of the subjects.

The president opened the first general meeting with an address (in German) on the progress and development of ornithology since 1910 (the last congress). In another meeting he spoke (in English) on "A Plea for More Scientific Collecting and Labelling." Other systematic papers were, among others: Stresemann (Berlin) on distribution and grouping of some African groups of birds; Heim de Balsac (Paris) on the supposed identity of *Cinclus cinclus* L. and *Cinclus cinclus aquaticus* Bechst; Lönnberg (Stockholm) on the origin of the North American fauna; Sushkin (Petrograd) on hybrids of shrikes and of thrushes, and on a peculiarity of adaptive evolution in the insular faunæ; Chapman (New York) on the biological significance of altitudinal life zones; Rensch (Berlin) on the justification of ornithological systematic principles in other branches of zoology; Neumann (Berlin) on the genus Alisterus (New Guinea parrot); Murphy (New York) on the adaptive variation of the Tubinares. Of other papers might be mentioned Lucanus (Berlin) on the mental life of birds; Gröbbels (Hamburg) on various anatomical subjects; Verwey (Utrecht) on the biology of the heron in the pairing season, and on a fulmar with feathered feet; Boas (Copenhagen) lectured on the neck of birds.

Great interest was manifested in bird migration, and a number of papers dealt with this subject, especially Götz (Stuttgart) on relations between moult and migration, Drost (Heligoland) on migrations in the winter months, Geyr von Schweppenburg (Münden) on the migrations of *Sylvia curruca* (Lesser Whitethroat), Schenk (Budapest) on the value and elaboration of dates of migration, Weigold (Hanover) on bird migration on Heligoland, Jägerskiöld (Gothenburg) on bird ringing by the Gothenburg Biological Society. Hörtling (Finland) dealt with ornithological explorations in Finland, and Fleming (Toronto) with the Arctic collections in the Canadian National Museum.

A somewhat prominent feature of the Congress were the numerous lantern slides and the wonderful films, which were shown in the large and beautiful 'Palace Theatre.' Unforgettable will be the motion pictures from the Bird Islands of Chile and Peru by Drs. Frank M. Chapman and Murphy (New York), on the development of the young of Central European birds by Heinroth (Berlin), and, last but not least, on the last evening, Bengt Berg's films from the Upper White Nile, showing the wonderful bird life in those countries, among others the masses of migrants and the *Balæniceps rex* as well as large herds of elephants, etc. Gröbbels (Hamburg) attempted to explain the physiology of the flight of birds on a film. Lectures by Meinertzhagen (London) on bird life in the Himalayas, Jespersen (Copenhagen) on the frequency of birds over the High Atlantic Ocean, Jourdain (Ditchingham) and van Oordt (Utrecht) on the bird life of Spitsbergen, Krabbe (Copenhagen) on eider-ducks and Greenland falcons, by Helms and Hörtling and others, were accompanied by excellent lantern-slide projections. Lectures by Schoenichen (Berlin) and others dealt with bird protection

Rather amusing and interesting were the imitations of birds' notes and song by Stadler and Preiss (Nürnberg), partially by mouth and partially with the help of instruments.

Much hospitality was shown to the members of the Congress. A half-day excursion took place in chars-à-bancs over a great part of Seeland, by the ancient renaissance castles Helsingör (Elsinore) and Frederiksborg to the estate of the enthusiastic bird-lover Herr Jarl, who is protecting his park and wood as a Nature reserve. Many members listened there for the first time to the powerful song of the 'Sprosser' or northern nightingale. The Minister of Foreign Affairs invited the Congress to a sumptuous tea in the rooms of the Royal Rifle Club and adjoining gardens. The

art-mæcenas Herr Jacobsen invited the Congress to his place at the Carlsberg Brewery. In the 'theatre' the lectures of Stadler and Preiss were delivered, a sumptuous Danish supper was served in one of the rooms of the Art Gallery, and the promenade through the extensive gardens, in the light of the full moon and lit up by numerous lanterns and torches, will long remain in the memories of those present.

Another feature of great scientific interest was the visit to the collections in Herr Schiöler's hospitable house. These collections, more or less limited to the Danish possessions, including Greenland and Iceland, are a masterpiece of completeness. All birds are represented by some beautifully mounted specimens and numerous skins, as well as very large series of skeletons, and anatomical preparations. The collection is in every way as it should be, though such completeness can at present only be reached in birds from a limited area, and is the work of a lifetime. A morning was spent in the Zoological Museum of the University, where lectures and discussions took place.

Invitations for the seventh International Ornithological Congress had come from Tunis, Finland, and Holland. A small number of the members of the International Committee voted for Tunis, others for Finland, but an overwhelming majority for Holland. The general meeting of the Congress adopted, therefore, Holland, where the next Congress is to take place in 1930, in the large and comfortable new Colonial Institute in Amsterdam

The Lister Institute of Preventive Medicine.

THE annual report which was presented by the governing body of the Lister Institute to the meeting of members held on June 9 records another year of satisfactory progress. There has been only one substantial change in staff: Dr. A. T. MacConkey, who has been in charge of the serum laboratories at Elstree for twenty years, has retired, and is succeeded by Dr. G. F. Petrie. Dr. Muriel Robertson, after several years of absence through ill-health, has returned to work and will restore the protozoological laboratory to a working department. The activities of the staff are augmented by workers maintained by the Medical Research Council, the Foot-and-Mouth Disease Research Committee, the Rockefeller Foundation, the British Empire Cancer Campaign, and others who find in the Institute the facilities and atmosphere which they need.

Under Prof. Ledingham, the bacteriological department has pursued a variety of researches. Particular notice should be made of the inquiries into the invisible viruses of smallpox, vaccinia, and foot-and-mouth disease, and of those, due chiefly to Dr. J. A. Arkwright and Mr. Bruce White, into the variation and biochemical structure of the food-poisoning and other bacteria—questions which have an important bearing on the conception and differentiation of 'species.' The systematic classification, nomenclature, and identification of bacteria, upon which all good physiological and pathological work with them ultimately depends, are cared for by the National Collection of Type Cultures, maintained at the Institute by the Medical Research Council.

The biochemical department in charge of Prof. Harden, who has also acted as director of the Institute during Prof. C. J. Martin's absence on sick leave, has been continuing its work on hexosephosphates and alcoholic fermentation and on the concentration and possible isolation of vitamins; Dr. Zilva is supervising the preparation of large supplies of concentrated lemon juice for the Antarctic whaling expedition. Dr. Robison is following up his important discoveries of the phosphoric esters in blood and tissues and their hydrolysis by specific enzymes.

The department of experimental pathology is energised by the director and Dr. Chick, and in various directions they have extended the investigations of accessory food factors for which the laboratory is now so well known. Refinements of knowledge have led to technical difficulties, and the distinction which must now be made between vitamin A (which promotes growth) and the antirachitic vitamin D has made a good deal of previous work unsatisfactory and new experiments more and more complex. Dr. Boas has made the significant discovery that dehydration, however it is carried out, makes egg-white quite unsuitable as a sole source of protein, and indeed seems to confer on it almost poisonous properties. Long and laborious observations on the nutritional qualities of cows' milk show that diet is the important factor in determining its content in vitamin A, while the amount of sunlight the animal gets is the chief thing which influences the antirachitic value of its milk.

The finances of the Institute are superficially in good order, the past year's work leaving a balance of 14,000*l*. But the position is actually far from what it should be, for of a total income of 51,000*l*. no less than 36,000*l*. was derived from diagnosis fees and the sale of sera and vaccines. The demand for these products naturally varies with the vagaries of epidemics in different parts of the world, and the precarious nature of the income so obtained must hamper the governing body in extending the activities of the Institute along lines which involve long or permanent commitments. A reduplication of Lord Iveagh's splendid benefaction is much needed.

University and Educational Intelligence.

LONDON.—The following doctorates have been conferred:—*D.Sc.* (*Applied Statistics*) on Mr. G. M. Morant (University College) for a thesis entitled "A Study of Egyptian Craniology from Prehistoric to Roman Times"; *D.Sc.* (*Biochemistry*) on Mr. J. H. Quastel (Imperial College—Royal College of Science) for a thesis entitled (1) "The Relationship of the Chemistry of Resting Bacteria towards Bacterial Growth," and (2) "A Theory of the Mechanism of Oxidations and Reductions *in vivo*"; *D.Sc.* (*Zoology*) on Mr. F. W. R. Brambell (University College) for a thesis entitled "Oogenesis of the Fowl (*Gallus bankiva*)"; *D.Sc.* (*Engineering*) on Mr. E. Mallett (Imperial College—City and Guilds College) for a thesis entitled "Forced Oscillations, Electrical and Mechanical"; *D.Sc.* (*Geology*) on Mr. F. Raw for a thesis entitled "The Development of *Leptoplastus Salteri* and other Trilobites"; *D.Sc.* (*Physics*) on Dr. R. L. Smith-Rose for a thesis entitled "Some Recent Research in Wireless Direction Finding," and other papers; *D.Sc.* (*Zoology*) on Miss N. B. Eales for a thesis entitled "The Anatomy of the head of a Fœtal African Elephant," and other papers.

THE League of Nations' International Committee on Intellectual Co-operation held its eighth plenary session at Geneva on July 26-29 under the presidency of Prof. Lorentz. The British Empire was represented by Prof. Gilbert Murray and Sir J. C. Bose. Among the subjects discussed were: the means for securing profits for scientific workers in connexion with the industrial application of their discoveries, the organisation of an international system of scholarships for the promotion of science, the foundation of an international university for the training of

statesmen, diplomats, the study of political science, etc., the co-ordination of scientific bibliography, the foundation of an international meteorological office, and the establishment of an international museum office to improve the organisation of catalogues and promote mutual assistance by loans, exchanges, distribution of photographs, etc. Sitting as governing body of the International Institute of Intellectual Co-operation, the committee received its report, adopted a programme and drew up a budget. The Institute will have at its disposal this year the French Government's subsidy of two million French francs, the Polish Government's grant of 100,000 French francs and the Czechoslovak Government's subsidy of 15,000 gold francs. The committee emphasised the necessity of setting up national university information offices in countries where they do not already exist. It was decided to study the possibility of convening in 1927 a meeting of representatives of national committees of intellectual co-operation.

UNIVERSITY tutorial class (extra-mural) teaching and its problems form the subject of a paper by Mr. R. S. Lambert, hon. secretary of the Association of Tutorial Class Tutors, published in the June number of the *Bulletin of the Association of University Teachers*. The writer points out that as the classes are largely organised by the Workers' Educational Association, nearly every tutor finds himself connected with this body, becomes a member of it, shares in its propaganda, and finds many opportunities for service as a speaker in the meetings of trade union branches, cooperative societies and guilds, working men's clubs, etc., which form the students' recruiting ground. About half the classes are, he says, taken by lecturers holding a salaried post within a university, who take a single class or two classes, in addition to their internal work, or instead of part of it, and are paid a fee per class (8*l*. as a rule). The other half are taken by tutors giving the whole or a greater part of their time. Of these, about twenty-five hold permanent salaried posts as 'staff tutors' under the various Joint (University and W.E.A.) Committees, and thirty have no guaranteed salary or status, but are dependent for their livelihood on fees paid according to the number of classes they happen to be taking. The work is both physically and mentally exacting, and four or five classes per week (each class meets twenty-four times during the year) are enough to occupy a man's entire energies. It is clear that these extra-mural classes of adult three-year students constitute vitally important areas of contact between the universities and the community, and their development, which is proceeding rapidly, needs very close attention.

COMPARATIVE statistics of German university students in 1914 and 1925 show very remarkable changes in distribution among the various faculties. Students of medicine, the humanities, mathematical and natural sciences, and evangelical theology comprised in 1914 respectively 25, 21, 11, and 7 per cent. of the total numbers; in 1925 these percentages had shrunk to 11·5, 16, 8, and 3. Students of law, of political science, and of chemistry, on the other hand, increased from 17, 4, and 1 per cent. to 28, 15·5, and 5 per cent. The total number increased during the same period from 69,644 to 81,699, this last figure being smaller by nearly eight thousand than the corresponding figure for 1924. These statistics are taken from "Academicus," a useful handbook of information about German universities and polytechnics. The 1926 issue (published by Alfred Lorentz, Leipzig, price M2.40) includes, for the first time, particulars of the German-speaking institutions of Austria and Czechoslovakia.

Contemporary Birthdays.

August 14, 1861. Sir Richard Threlfall, K.B.E., F.R.S.
August 14, 1860. Dr. Arthur Prince Chattock, F.R.S.
August 15, 1842. Sir William A. Tilden, F.R.S.
August 15, 1871. Prof. Grafton Elliot Smith, F.R.S.
August 16, 1863. Prof. Frederic Stanley Kipping, F.R.S.
August 18, 1831. Mr. Ernest Noel, F.G.S.
August 19, 1868. Prof. William Bulloch, F.R.S.

Sir RICHARD THRELFALL, who was born at Hollowforth, Lancashire, was educated at Clifton and Caius College, Cambridge. He is chairman of the Fuel Research Board.

Dr. CHATTOCK was born at Solihull, Warwickshire. He is emeritus professor of experimental physics in the University of Bristol.

Sir WILLIAM TILDEN, the veteran chemist, to whom we offer our very hearty congratulations on the celebration of his eighty-fourth birthday, was born in London. Formerly a science master at Clifton College, he occupied next the chair of chemistry at Mason College, Birmingham. On leaving there he became professor of chemistry at the Royal College of Science, London, retiring in 1909. The Royal Society had awarded him in the previous year its Davy medal for his discoveries in chemistry. Sir William gave the Mendeléeff Memorial Lecture before the Chemical Society, in 1909, in all respects a masterly exposition. Incidentally, we may recall that Mendeléeff's last appearance in London was in November 1905, when he attended to receive the Copley medal of the Royal Society.

Prof. G. ELLIOT SMITH was born at Grafton, N.S.W., and educated at the Universities of Sydney and Cambridge. Formerly professor of anatomy in the University of Manchester, he now occupies a similar chair in University College (University of London). In 1912 the Royal Society awarded him a Royal medal in recognition of distinctive investigations on the comparative anatomy of the brain. Prof. Elliot Smith is the author (among many works) of "The Evolution of Man" (1924), and holds original views on the origin and diffusion of culture.

Prof. KIPPING was born at Manchester and educated there at the Grammar School, at Owens College, and at the University of Munich. For some time he was on the teaching staff of Heriot-Watt College, Edinburgh, and next became a lecturer in chemistry at the Central Technical College, London. In 1897 Prof. Kipping was appointed to the chair of chemistry in University College, Nottingham. The Royal Society awarded him its Davy medal in 1918 for his investigations in organic chemistry.

Mr. ERNEST NOEL, who is in his ninety-fifth year, is the *doyen* of the Geological Society of London. Educated at Edinburgh and Trinity College, Cambridge, he was elected into the Geological Society in 1849, and thus has been seventy-seven years on its roll.

Dr. WILLIAM BULLOCH was born at Aberdeen and educated there at the University. Formerly assistant professor of pathology in University College, London, he has been, since 1919, Goldsmiths' professor of bacteriology in the University of London. He is Hon. LL.D. Aberdeen.

Societies and Academies.

PARIS.

Academy of Sciences, July 5.—Gabriel **Bertrand** and M. **Mâcheboeuf**: The influence of nickel and cobalt on the action exercised by insulin on the dog. The results of experiments carried out on the rabbit have been given in an earlier communication: it is now shown that the addition of cobalt and nickel to insulin causes similar effects on the dog and rabbit. There is an increase in activity in both animals; cobalt has a greater influence than nickel.—Gaston **Julia**: A series of polynomials connected with the conformal representation of simply associated areas.—Luigi **Fantappiè**: Analytical functionals which are functions of a finite number of linear functionals.—René **Lagrange**: Legendre functions of the first species and certain associated functions.—N. **Gunther**: The movement of a liquid filling a simply associated domain which is displaced.—Henri **Bénard**: The deviations of the values of the frequency of vortices alternating with respect to the law of dynamical similitude.—Th. **De Donder** and Fr. H. **van den Dungen**: The quantification deduced from Einsteinian gravific.—Léon **Brillouin**: The undulatory mechanics of Schrödinger, a general method of resolution by successive approximations.—W. H. **Keesom**: Solidified helium (*v.* NATURE, July 17, p. 81).—Jean **Lecomte**: Infra-red absorption spectra of cyclic derivatives. The infra-red absorption spectra of derivatives of benzene, cyclohexene, and cyclohexane have been compared and numerical data are given.—René **Lucas**: The rotatory power of tartaric acid. The effects of the addition of such substances as boric acid, tungstic acid, urea, etc., can be explained as being due to the appearance of one new form, strongly dextrorotatory, and in proportions varying with the reagents. It is possible that the anomalies of malic acid follow a similar mechanism.—P. **Daure**: The qualitative study of the fluorescence of bromine vapour.—R. de **Mallemann**: Magnetic rotatory dispersion and the dispersion of electric double refraction. From theoretical considerations it is concluded that the ratio of Verdet's constant to Kerr's constant should vary inversely as the wave-length, or, alternatively, the ratio of the magnetic rotatory dispersion to the dispersion of electric double refraction should be equal to the corresponding ratio of wave-lengths. This conclusion is verified experimentally for carbon disulphide and for camphor in hexane solution.—Paul Gabriel **Girault**: A possible influence of commutation on the stability of continuous current machines.—Georges **Fournier**: The absorption of β-rays by matter.—D. P. **Konovalov**: The heats of combustion of some hydrocarbons. Values are given for the heats of combustion of cyclohexene, methylenecyclohexane, and dicyclohexane and the figures compared with those calculated from a formula given by the author in an earlier paper.—A. **Boutaric** and G. **Corbet**: On the critical temperature of solution of acrolein and water and on the molecular mass of soluble acrolein resin. The soluble acrolein resin studied is a polymer of ten molecules of acrolein.—— **Surun**: The estimation of the adsorbing power of carbons.—E. **Rouyer**: The determination of some double salts in solution by the boiling point method. Experimental data for the double sulphate of ammonium and RSO_4, where R is cadmium, iron, cobalt, manganese, zinc, magnesium, copper, and nickel, and also double chlorides of the carnallite type.—— **Holweck**: The spectrometry of the *K* series of the light elements. The *K* discontinuity of fluorine. The advantages of the method of critical potentials are emphasised; it brings out the *K* discontinuity of fluorine at 684·2 volts very clearly. By combining the results of several workers, the Moseley curve from helium to sulphur is shown to be a straight line.—V. **Ipatief** and A. **Andreevsky**: The displacement of platinum by hydrogen under high pressures. The precipitation of platinum from its solutions by hydrogen is a function of the temperature, pressure, concentration, and time, and results of experiments in which each of these factors was varied are given. The presence of metals such as iron and nickel, especially in acid solution, tends to retain platinum in solution.—Daniel **Florentin**: The estimation of soluble silica in cements, mortars, and concretes.—Georges **Denigès**: The action of concentrated hydrobromic and hydriodic acids on the cobalt ion. A new reaction for nickel. A description of new colour reactions of cobalt with concentrated hydrobromic and hydriodic acids and of nickel with concentrated hydriodic acid.—André **Job** and Antoine **Cassal**: The fixation of carbon monoxide on an organic magnesium compound by means of chromic chloride. A solution of phenylmagnesium bromide is without action upon carbon monoxide, but the addition of anhydrous chromium chloride causes an immediate absorption of the gas. From the products of this reaction benzopinacone, benzophenone, benzhydrol, diphenyl, diphenyl-acetophenone, and benzaldehyde were isolated. Some chromium-carbonyl is also produced.—Marcel **Delépine**: A supposed isomer of methylene-amino-acetonitrile. Methylene-bis-iminodiacetonitrile. The substance previously described as an isomeride of methylene-aminonitrile is proved to be the methylene derivative of imino-diacetonitrile.—Emile **Votoček** and F. **Valentin**: The optical inverse of natural rhamnose. Starting with isorhodeonic acid, *d*-rhamnose has been prepared; it has all the properties of natural rhamnose except that its rotation is of opposite sign.—F. **Salmon Legagneur**: The action of ethyl-magnesium bromide on the methyl ether of the α-mononitrile of camphoric acid. The products of the reaction are α-ethylidene-camphidone and a secondary nitrile alcohol.—Octave **Bailly** and Jacques **Gaumé**: The synthesis and hydrolysis of glyceromonophosphoric di-ester; α,β-diglyceromonophosphoric acid and the constitution of orthophosphoric acid.—René **Delaplace**: The preparation of cæsium eosinate. Cæsium hydroxide is treated with the theoretical quantity of acid eosin to prepare the eosinate. Details are given of the preparation of the eosin and of the cæsium hydroxide, together with the method of recovering the cæsium.—— **Viret**: New observations relating to the rodent fauna of Saint-Gérand-le-Puy.—Mlle. G. **Bonne**: The nature of the floral section in the Chrysobalaneæ.—M. **Bridel** and C. **Béguin**: A new glucoside, hydrolysable by rhamnodiastase, extracted from the fresh flowers of *Ulex europæus*. Details of the extraction, chemical and physical properties of a new glucoside, to which is given the name ulexoside. This gives the methylpentose reaction, and can be hydrolysed by rhamnodiastase giving a sugar and ulexogenol.—A. **Sartory**, R. **Sartory**, and J. **Meyer**: The study of the action of radium on *Aspergillus fumicatus* in culture on dissociated and non-dissociated media.—M. and Mme. A. **Chauchard**: The action of curare on the electrical apparatus of the torpedo (*Torpedo marmorata*). The curarisation of the electrical apparatus of the torpedo necessitates the use of relatively large doses of curare. The poison does not act on the nerve but on the electrical organ.—G. A. **Nadson** and M. N. **Meisl**: The mechanism of the action of chloroform on living matter. Description of the action of chloroform on

a yeast (*Saccharomyces Ludwigii*), the observations being so arranged that the same cell was studied throughout.—Pierre **Girard** and Edouard **Peyre**: The suppression of shock and modification of the anaphylactic sensibilisation by certain fluorescent colouring matters. The colloidal mechanism.—Charles **Pérez**: Some secondary sexual characters in Galathea.—Louis **Roule** and Léon **Bertin**: The development with complex metamorphoses (hypermetamorphosis) of *Nemichthys scolopaceus*.—Paul **Mathias**: The evolutive cycle of a trematode of the family of the Echinostomidæ (*Echinoparyphium recurvatum*).—Robert **Regnier** and Roger **Pussard**: The constitution of the reserve stores of *Microtus arvalis* (field mouse), and its importance for the multiplication of this rodent.—E. **Aubel** and L. **Genevois**: Researches on the reduction of thionine by various organic substances, in the absence of air and light.—L. **Lutz**: The soluble ferments secreted by the Hymenomycetes. Oxidising actions.—J. **Sabrazès**: Spirochætes in experimental peritonitis by intestinal perforation in the guinea-pig.

CAPE TOWN.

Royal Society of South Africa, June 16.—K. H. **Barnard**: A study of the freshwater isopodan and amphipodan Crustacea of South Africa. A general account of the biology of *Phreatoicus capensis*, including a curious habit of æstivation, and certain tendencies to variation, is given *P. capensis* is closely allied to *P australis*; both forms are regarded as being the direct descendants of the ancestral stirps represented by the fossil species *wianamattensis*. A freshwater isopod of the family Jæridæ having affinities with the Australian genus *Heterias* is described Several new species of 'blind' gammarids are described; the localised habitat of these 'blind' species is contrasted with the wider distribution of the single black-eyed species *Phreatoicus capensis* is confined to old and mature valleys in the less highly tilted mountains, and is not found now outside the limits of the effective deposition of moisture from the clouds formed by the S.E Trade winds The finding of a fossil species of Phreatoicus shows that the tribe was both austrogenic and palaegenic, and rules out the theory of a migration of northern Crustacea via the Andes into Australasia—S H **Haughton**: The river system of S W. Gordonia: In the last few miles of its course, the Molopo River shows all the characters of rejuvenation impressed upon a mature stream—waterfalls, a winding deep gorge, and old river-gravels This rejuvenation is due to the recession of the Aughrabies Falls past the mouth of the Molopo and the consequent cutting-back of the Molopo Falls to their present position. There is no permanent stream in the Molopo now. The tributaries of the Orange to the west of the Molopo in Gordonia have arrived at a more mature stage, although they are deeply entrenched. The cessation of erosive action in S.W. Gordonia seems to have been an event of geologically recent date.—B. F J. **Schonland** and J. **Craib**: Measurements of the electric fields of thunderstorms. An observatory for the study of electrical meteorology was established on the farm Gardiol, near Somerset East, in January 1926, and a photographic recording apparatus similar to that designed by C. T. R. Wilson has been in use.

ROME.

Pontifical Academy of Sciences (Nuovi Lincei), May 24.—**Stein**: Double stars in the astrographic catalogue of the Vatican zone.—**Colonnetti**: Experimental investigations on elastic co-actions.—**Sesini**: Elastic co-actions.—**Pugno**: Study of the compensators in use in optical experiments on elasticity.—**Luigioni**: New species of blind coleoptera (*Duvalites Franchetti*) discovered by Baron Carlo Franchetti in a grotto near Subiaco (Central Italy).—**Luigioni**: The specific validity of *Anoxia sicula*.—**Pagnini**: The hypotheses serving as foundation for the undulatory theory of light.—**Palazzo**: Geophysical observations relating to the total eclipse of the sun.—**Palazzo**: The magnetic contour of Somaliland.—**Silvestri**: Pseudo-nummulites in the tertiaries of Tuscany.

SYDNEY.

Linnean Society of New South Wales, May 26.—Rev H. M. R. **Rupp**: Further notes on the genus Pterostylis. Records are given of five additional species, together with corrections and additions to some of the previous notes on the genus.—E. W. **Ferguson**: Revision of Australian Syrphidæ (Pt. 1). Little attempt has hitherto been made to deal systematically with the Australian species. Keys for the separation of the subfamilies, and for the identification of the species of Cerioides, Eristalis, Helophilus and Microdon are given. Twenty-three species are described as new.—P. D. F. **Murray**: An experimental study of the development of the limbs of the chick. Grafts on to the chorio-allantoic membranes of seven-day chicks, of the limb buds and fragments of limb buds of three-, four- and five-day chicks, and of limb *anlagen* at earlier stages, show the limb *anlagen* to have in a high degree the power of self-differentiation, their development being apparently independent of other regions of the chick, except for the blood supply. The limb bud is a mosaic structure Ends of skeletal elements may develop normal joint structures in the absence of the neighbouring element upon which the joint would normally work—R **Greig-Smith**: The influence of certain colloids upon fermentation (Pt. 3). Fuller's earth and aeration in the alcoholic fermentation Judging by the action of fuller's earth, the mineral colloids have an action of their own in accelerating the activity of yeast in the fermentation of dextrose. Their faculty of assisting the dispersal of dissolved carbon dioxide does not explain their action, for when the fermenting fluids were aerated, the colloid still hastened the fermentation.

VIENNA.

Academy of Sciences, June 17.—V. **Oberguggenberger**: The scintillation of the stars. A coarse diffraction grating was fixed to a telescope so that the grid was parallel to the daily motion. The telescope being fixed, the star traversed the field and showed a spectrum trace on the photographic plate. In this way the Innsbruck Observatory has examined the frequency of the scintillation.—G. **Rzimann**: The formation of organs from adventitious buds in *Tolmiea Menziesii*. An attempt to trace the influence of the ratio between carbohydrates and mineral salts in forming leaves or roots.—M. **Kofler**: A simple definition of the inconstancy of a natural phenomenon.—J **Pircher**: An apparatus for registering the squalliness of the wind connected to a Dines' anemograph.—V. **Conrad**: Fluctuations of seismic activity in various fold-regions.—A. **Wagner**: Wind registrations on the 150-metre high radio tower at Altenburg, Germany.—W. **Schmidt**: Experiments with models on the influence of the rotation of the earth on the course of rivers.

Diary of Societies.

SATURDAY, AUGUST 14.

MINING INSTITUTE OF SCOTLAND (at Glasgow).

WEDNESDAY, AUGUST 18.

CORRELATION OF SCIENCE SOCIETY (at Royal Botanic Society of London), at 3.—Conference on Partial Impact and Whirling Coalescence.

SATURDAY, AUGUST 21.

NORTH OF ENGLAND INSTITUTE OF MINING AND MECHANICAL ENGINEERS (Annual Meeting) (at Newcastle-upon-Tyne), at 2.30.

CONGRESSES.

AUGUST 27 AND 28.

IRON AND STEEL INSTITUTE (Autumn Meeting) (at Stockholm).—F. Adcock: The Effect of Nitrogen on Chromium and some Iron Chromium Alloys (Alloys of Iron Research, Part IV.).—J. H. Andrew and H. A. Dickie: A Physical Investigation into the Cause of Temper Brittleness.—Prof. C. Benedicks, H. Backstrom, and P. Sederholm: Anomalies in Heat Conduction, with some Determinations of Thermal Conductivity in Iron and Carbon Steels. Prof. C. Benedicks and R. Sundberg: Electrochemical Potentials of Carbon and Chromium Steels.—G. F. Comstock: The Treatment of Steel with Ferro Carbon-Titanium. G. A. Hankins, D. Hanson, and Miss G. W. Ford: The Mechanical Properties of Four Heat-Treated Spring Steels.—Prof. K. Honda: Is the Direct Change from Austenite to Troostite Possible?—A. Johansson and R. Von Seth: The Carburisation and Decarburisation of Iron and Some Investigations on the Surface Decarburisation of Steel.—A. Johansson and A. Wahlberg: The Development of the Swedish Iron and Steel Industry during the last thirty years.—E. Kinander: Notes on Jernkontoret.—A. Lundgren: The Testing of Hardened Steel.—W. Petersson: Notes on the Development of the Swedish Mining Industry during the last twenty-five years.—G. Phragmen: The Constitution of the Iron-Silicon Alloys.

AUGUST 29 TO SEPTEMBER 1.

SOCIÉTÉ HELVÉTIQUE DES SCIENCES NATURELLES (at Fribourg).—In Sections devoted to Mathematics, Physics, Geophysics, Meteorology and Astronomy, Chemistry, Geology, Mineralogy and Petrography, General Botany, Special Botany and Geographical Botany, Zoology, Entomology, Anthropology and Ethnology, Palæontology, Medical Biology, History of Medicine and Natural Science.

AUGUST 31 TO SEPTEMBER 8.

WORLD POWER CONFERENCE (at Basle), Technical Programme of Sectional Meeting:

Utilisation of Water Power, and Inland Navigation.
Exchange of Electrical Energy between Countries.
The Economic Relation between Electrical Energy Produced Hydraulically and Electrical Energy Produced Thermally: Conditions under which the two systems can work together with advantage.
Electricity in Agriculture.
Railway Electrification.

SEPTEMBER 1 TO 4.

INSTITUTE OF METALS (Autumn Meeting) (at Liege) (September 1, at 8.—Dr. W. Rosenhain: Ancient Industries and Modern Metallurgy) (Autumn Lecture).—Dr. C. J. Smithells, H. P. Rooksby, and W. R. Pitkin: The Deformation of Tungsten Crystals.—Prof. K. Honda: A Comparison of Static and Dynamic Tensile and Notched-Bar Tests.—C. H. M. Jenkins: The Constitution and the Physical Properties of the Alloys of Cadmium and Zinc.—H. J. Gough, S. J. Wright, and Dr. D. Hanson: Some Further Experiments on the Behaviour of Single Crystals of Aluminium under Reversed Torsional Stresses.—B. Ôtani: Silumin and its Structure.—G. B. Phillips: The Primitive Copper Industry of America. Part II.—Kathleen E. Bingham: The Constitution and Age-Hardening of Some Ternary and Quaternary Alloys of Aluminium containing Nickel.—Dr. A. G. C. Gwyer and H. W. L. Phillips: The Constitution and Structure of the Commercial Aluminium-Silicon Alloys. With an Appendix upon The Properties of the Modified Aluminium-Silicon Alloys, by Dr. D. Stockdale and I. Wilkinson.—J. D. Grogan: Some Mechanical Properties of Silicon-Aluminium Alloys.—Dr. C. S. Smith and Prof. C. R. Hayward: The Action of Hydrogen on Hot Solid Copper.—Capt. F. R. Barton: The Development of the Use of Nickel in Coinage.—A. Pinkerton and W. H. Tait: Season-Cracking in Arsenical Copper Tubes.—Prof. P. Chevenard: Thermal Anomalies of Certain Solid Solutions.—W. Educational Training for Overseas Life.

NOT the least significant feature of the third report of the Committee appointed by the British Association to consider the Educational Training of Boys and Girls for Overseas Life, presented at the Oxford meeting, is the emphasis which is laid upon the social importance of agricultural and other practical studies. The Committee rightly states that the intellectual and cultural aspects of practical studies are too often overlooked or regarded with contempt by educational authorities who fail to appreciate the clearer vision which accompanies contact with reality and the greater interest which practical work, even if vocational in aim, arouses in the pupils themselves. As Mr. H. W. Cousins aptly remarked, in the discussion on the report, the purpose of education should be to create an interest in doing things, not in merely talking about them, a sentiment which was warmly applauded by H.R.H. the Prince of Wales, who was present.

While it is true that the work of Prof. Nunn and other educationists is gradually modifying the attitude of teachers in schools towards practical work—not merely work in a chemical or physical laboratory—it is equally true that their efforts to combat 'education by book' are hampered and discouraged by most examining bodies. The capacity of the 'bookish' pupil is easier to assess than that of the pupil whose main interest lies in acquiring understanding of, and the capacity of participating in, the activities of his particular environment. A board of examiners sitting in one of the great centres of learning, however well intentioned, must find it exceedingly difficult catering for the needs of pupils in various environments, whose education is 'practical' and suited to the special environment, but of which the examiners themselves can know very little. Their difficulties would be increased if education authorities in those of our overseas territories, which are connected for examination purposes with English universities, desired to develop a schools curriculum based on the special needs of the countries they serve.

The point might well have been made by the Committee on Overseas Training that the education of boys and girls in our Dominions, Dependencies, and Crown Colonies is more 'bookish' and less adapted to make them capable of 'deliberate adjustment to their environment'—after all, the true purpose of education—than that which is given at home. There, those who are charged with the responsibility for the evolution of a system of education have generally accepted unreservedly the system evolved to suit a very different environment. Instead of basing their system upon the needs of the many, they have subordinated it to

the English examination system in order to cater for the needs of the very small number of pupils who may proceed to England to pursue their further studies. Certain education authorities in Ceylon, it is stated, send to a biological station in England for specimens of British marine and other material prescribed for study by one of our examining bodies. It would seem obviously the better course for the examining body to prescribe for study some of the specimens which abound in Ceylon.

Kenya Colony, the only East African territory where public provision is made for the education of European children, is an abject slave to the tyranny of the London Matriculation and the Oxford and Cambridge Local (so called) examinations. Most of the children educated in the State schools in Kenya will certainly never leave East Africa for a further course of study in Great Britain. The environment to which they have to adjust themselves is essentially agricultural; an environment which demands an understanding of the black races, and a sound knowledge of the elementary principles of social and personal hygiene, and human, animal, and plant diseases; in other words, an education where the bias should be agricultural and otherwise practical, where work in the field and workshop and laboratory should be the basis of the instruction in science and elementary anthropology the basis of the 'humanistic' studies. Nothing of the kind has been attempted. The syllabus of instruction is that prescribed for the 'literary' side of the English examinations; there are no workshops, there are no laboratories, there is no provision for practical work in the field. Where 'science' instruction is given at all it is 'out of the text-book.' What knowledge the children have of the native races is acquired in a school of experience which is calculated to breed contempt for them, and sow seeds of racial antagonism. Both the blacks who come within the sphere of influence of the State schools, and the Indian children, are being better educated than the children of the Europeans.

The most obvious commentary upon the type of instruction given in schools in Australia is the disproportionate size of its cities. Appeals for immigrants are made to compensate for the flight of colonial-born agriculturists from the land to the social amenities of towns, and the reluctance of Australia's urban unemployed to transfer to the land. Much the same problem faces all our self-governing dominions. This problem of education is of world-wide significance and of especial importance to the British nation, which bears a grave burden of responsibility for the development of so great a proportion of the world's natural resources and of the backward races. It is sufficiently important to command much of the attention of the statesmen of the Empire who will shortly be gathered together for another Imperial Conference. Education is not a subject remote in its bearings upon Imperial policy; it lies at the root of it. Upon the type of instruction which is given in our educational institutions at home will depend largely the character and outlook of the administrators of the scientific and technical experts in tropical possessions, and of the settlers in British dominions. Administrators could be produced whose training and educational achievements would be a guarantee that they would combine understanding of the problems inherent in the development of the natural resources of a country and the development of the soul of a people; and the scientific and technical services could be manned by those who combined knowledge of their craft with understanding of primitive crafts and a realisation of the social and political significance of the introduction of European ideas and processes among backward peoples.

If the needs of the better instructed elements among the Britons who proceed overseas are such as to demand considerable changes in the education which is given them as a preliminary training, the needs of the secondary school boys and girls destined for overseas work is greater. Whether they go to the tropics, where they must perforce have intimate contact with backward peoples, or to the self-governing dominions, there are certain obstacles which 'personality' alone cannot overcome, but 'character' based upon knowledge, capacity, and grit can. Prejudice against a newcomer wishing to introduce new methods into production is the commonest of diseases. But prejudice is not best overcome by pandering to the 'oldest inhabitants' fixed notions of what is right, but by proving the greater efficiency of the new. It is doubtless true, as Mr. Ormsby-Gore said at Oxford, that overseas farmers prefer to deal with 'raw' rather than instructed new settlers, that they prefer a man who has had no agricultural training in England to the man who has, because the methods overseas are vastly different from those at home. It does not follow, however, that the overseas man on the spot is sound in his prejudices. His methods may be thoroughly unsound. The home-trained man's methods, even applied in a new country, may be thoroughly sound in principle.

The most important aspect of the problem of land-settlement is the outlook of the settlers upon their work. Not the least significant feature of the flight from the land is the material sacrifices which those who are forsaking agriculture are prepared to make for the greater amenities of town life. The only apparent remedy lies in an education system which will bring greater contentment to the comparatively

isolated land worker. It is not easy to prescribe the exact form which this remedy must take, but it is fairly clear that it must depend upon the quickening interest of the workers in their vocation. No greater harm could be done to the cause of agriculture than by ceaseless reiteration of the material benefits arising from its pursuit. There is a limit to credulity and gullibility.

What is wanted is for the Imperial Conference to take an intelligent interest in this problem. It is more vital than tariffs; without even a partial solution much of the work of the politician and financier and trader will be wasted. An Imperial Education Committee is of more importance even than an Empire Marketing Board. It will not suffice to refer the problem of education to a committee of expert educationists; the responsible leaders among the statesmen of the various dominions and Crown colonies must be prepared to consider the whole problem with the experts and to make their own contribution to the discussions. They must let the educationists know what they hope from them: they must be prepared to fight for the necessary changes in educational policy in the countries for which they are responsible. Above all, they must assist the true educationist to rid himself of the examination blight. They must encourage a spirit of experimentation in educational method and realise that a stereotyped Prussian system of instruction, towards which we have been retrogressing while even the Prussians themselves have commenced to react against it, will kill the soul of any people.

The eminent persons who spoke at Oxford, ostensibly in support of the recommendations of the Overseas Training Committee, cannot be said to have laboured the essential features of the report. They gave the impression that a social veneer was a greater attribute to a man than social qualities. It cannot be overemphasised that the latter depend upon knowledge based upon a sound education system. According to one speaker, it was more important for a man proceeding overseas to have gone to the right type of school than it was for him to have acquired the right kind of knowledge, based upon an intensive technical training. It is a pity it is not more generally recognised that this curious snobbery is responsible for more of the defects in our administration system and our comparative failures in Imperial affairs than any other factor.

One other point which emerged in the discussion is of some interest, and this is the one which was raised by Mr. Ormsby-Gore in connexion with the staffing of the education and scientific services in the Crown Colonies. He stated that the Crown Colonies are in the greatest need of expert educationists and first-class scientific advisers. At present the demand exceeds the supply and it is impossible to fill many of the vacancies which existed. This he contrasted with the ease with which the late German administration in East Africa had built up its wonderful research institutions. It can only be hoped that this was not special pleading on the part of Mr. Ormsby-Gore to justify the chronic neglect of the British administration of once world famous institutions. The fact is that it is only within the last two years that the slightest appreciation has been displayed, either by the local governments of East Africa or by the Colonial Office, of the obvious fact that upon the education and scientific services the whole future of East Africa will depend. There would be no difficulty in obtaining the personnel for either of the services if the proper inducements were offered, and if the Colonial Office and the other governments would realise that it is not merely material inducements which will make the East African services attractive: conditions of service are just as important as salary, and the Colonial Office should realise that it is sometimes possible to offer a large salary without attracting candidates, because the acceptance of the post would rob the man appointed of all title to the respect of his fellows.

Indian Witchcraft and Primitive Forms of Belief.

Religion and Folklore of Northern India. By William Crooke. Prepared for the Press by R. E. Enthoven. Pp. iv. + 471. (London: Oxford University Press, 1926.) 21*s*. net.

WHEN the history of the study of 'things Indian' is written, the name of the late William Crooke will rank high. His erudition was vast, and his range of reading immense, while his sanity of outlook and grasp of matters of fact guided him among the many pitfalls which have beset the paths of theory in Indian ethnology. It was these qualities which made him a particularly safe guide to the student and accounted largely for the high repute of the pioneer work in his little book "An Introduction to the Popular Religion and Folklore of Northern India," first published in 1894. It was reissued in 1896, and is now published posthumously in a third edition, but entirely rewritten in the light of further information.

It is scarcely necessary to stress the importance of Crooke's work in the study of the primitive religions of India. His contact with the village population in the course of his duties as an official of the Civil Service led him to the study of their beliefs and ritual. These he found represented a type very different from those of the priestly class and those described in the sacred books of the Brahmans. His investigations ranged

over the whole of northern India to the Nerbada River, and took in the population of the west coast and the Deccan. This area had been overrun by many waves of foreign incursions flowing over an indigenous population. Its inhabitants included primitive Mongoloids, represented by the tribes of the Assam frontier and the Kols and allied tribes, Dravidians such as the Gonds and Oraons, and in the Punjab, Indo-Aryans, Persians, Greeks, Sakas, Indo-Parthians, Huns, and Mongols.

The study of this medley of races revealed that the superficial uniformity of the widely adopted Hinduism embraced a variety of beliefs ranging from primitive animism to the worship of deities of the orthodox pantheon. In fact, Crooke's researches showed that while some conformed to Hinduism, owing to the rise in social status which followed the adoption of Brahmanism, and yet retained the cults of their tribal deities, others regularly resorted to the village, caste, or tribal godling in times of crisis, drought, famine, or pestilence. On the other hand, there went on *pari passu* a process of adoption of the godlings of the animistic peoples into the Hindu pantheon. Of such were the benign Devi, traced back to one of the manifestations of Dharti, the earth mother, Kali, a deified tigress, and on a lower scale not yet fully of orthodox rank, Hanuman the ape and Ganesa the rat. These latter are the Dvārāpalas, 'doorkeepers,' of the temple of the greater gods. The story of these local deities and of their development out of the strictly local cult into a more widely, or even generally, recognised object of worship is a pregnant chapter in the history of religion.

It is not without significance, and it is at the same time interesting to note, that among the many heroes who are objects of a cult appear the names of several Englishmen and an Englishwoman, whose tombs are treated with special reverence and to whose spirits offerings are made. The ghost of Capt. Cole, killed in 1804, is propitiated with offerings of wine and cigars; another, the spirit of a bibulous official, with beer and whisky; while the tomb of Col. W. Wallace of Sirur in Poona is worshipped on Thursdays and Sundays "in fulfilment of vows made for the cure of barrenness."

It would be difficult to single out any one topic as especially worthy of mention where so much is of interest and importance, whether in relation to the more primitive forms of belief among the Indian peoples themselves, or as affording material for comparative study. There is, however, one line of inquiry for which the religious, social, and racial conditions make northern India an especially promising field. Dr. Crooke's last chapter deals with the black art and witchcraft—a subject which offers occasion for many interesting questions. What, for example, is the relation between practitioners of white and black magic, and at what stage of development do they become differentiated? The Shaman, or medicine man, who may, and indeed often does, practise both forms of magic, develops on one hand into the orthodox magician or priest whose function is normally exercised to the advantage of his social group and its members, on the other into the witch whose action is malevolent and anti-social. The priest may still practise black magic, as do some Brahmans, with impunity. The Jackdaw of Rheims was cursed 'by book and by bell' as effectively as if he had been the victim of the blackest magic. The witch is destroyed or cast out.

The term 'witchcraft' is constantly used loosely in describing magical practices of primitive peoples, but it should imply more than the occasional use by any individual of magical practices for malevolent purposes. The witch of northern India as described by Dr. Crooke is one who performs harmful acts through the control of evil spirits. In European witchcraft, while the basis of the belief was purely magical, as can be seen even in the Bull of Innocent VIII., where the witch was said to blast crops, harm cattle, and bring disease and death to human beings—just as the Indian witch—yet the essential element in the legal and theological definition of a witch was the fact that she had entered into a compact with the devil from whom her power was derived. This no doubt goes back to the practice of the early Christian Church, which regarded backsliders into paganism as devil worshippers, and witchcraft was closely connected with heresy. But it is also significant that the Templars, who were reputed to have brought their alleged magical practices from the East, were accused of trafficking with and controlling evil spirits.

Indian witchcraft affords some curious and interesting parallels to the European belief. The witch is marked out by her appearance. Dhanwārs in the Central Provinces, for example, detect a witch by the sunken and gloomy appearance of the eye. Ovid mentions a double pupil as characterising a witch; in Wales she can be detected by the inversion of the image reflected in the eye. Unlike the European witch, almost invariably a hag, the Indian witch is beautiful. The witch acquires her art by a course of instruction. Among the Santals the novice, with a lamp in her hand and a broom tied to her waist—note the appearance of the broom—is taken to be married to one of the Bongas or spirits. The parallelism of the European methods of initiation is not exact but is sufficiently close. Again, Indian witches possess familiars, a cat or a tiger, and they themselves take on animal form. The use of a waxen image to harm an enemy, a practice which goes back to early Babylonia and Egypt, and is familiar in European witchcraft, is also noted. One of

the most remarkable feats of the Indian witch in this connexion is the 'abstraction of and eating a man's liver,' of course without his knowledge until he realises that he has been bewitched and in what manner. European witches sometimes 'extracted the heart' in much the same way. Finally, in both Europe and India a witch is detected by casting her into water to see if she will sink or float.

We may conclude with a much travelled story. Lona, an Indian witch noted in legend, performed an incantation for a young man over a hair supposed to belong to the object of his affections. Unfortunately for him, he had been deceived by a slave and the hair had been taken from a sieve which burst into the room immediately the magical rite had been performed. The same story is told of John Fian, the leader of the witches who conspired against James I.; but in his case the hair was that of a heifer, which incontinently pursued him, to his great embarrassment and confusion.

Storm and Stress.

(1) *Pleasure and Pain: a Theory of the Energic Foundation of Feeling.* By Paul Bousfield. Pp. x+114. (London: Kegan Paul and Co., Ltd.; New York: E. P. Dutton and Co., 1926.) 4s. 6d. net.

(2) *The Adolescent Girl: a Book for Parents and Teachers.* By Dr. Winifred Richmond. Pp. xv+212. (New York: The Macmillan Co., 1925.) 5s. net.

(3) *The Gang Age: a Study of the Preadolescent Boy and his Recreational Needs.* By Dr. Paul Hanly Furfey. Pp. xiv+189. (New York: The Macmillan Co., 1926.) 8s. 6d. net.

OF recent years, emotion as the driving and guiding principle, which shapes our lives and determines our behaviour, has occupied the attention of psychologists to a greater and greater extent. More particularly have they attempted to study from a scientific aspect that period of difficulty through which every boy and girl must pass as the simpler adjustments of the home give place to the wider emotional relationships of society. To the individual adolescent the period is still as stormy as it was to Goethe, and the adult is only groping his way to an understanding which will enable him to help. The question of what emotion is remains unsettled, and while all authorities regard the affective reactions of pleasure and pain as important constituents, they are by no means unanimous as to their exact relation to appetite, instinct, and emotion.

(1) Dr. Bousfield has approached the problem of pleasure and pain by attempting to explain the apparent paradox of the pleasure of enduring pain. First of all, he maintains that the fundamental disposition in all animals is a reaction to stimuli in such a way that tension will be reduced. Even such instincts as self-preservation and race preservation are not innately given, but the result of social influences in each generation. He demonstrates the rise and fall of tension by means of diagrams, and points out that pleasure does not exactly correspond to the fall of tension, since the maximum of pleasure depends rather on the rate than on the extent of the fall.

During life, tension is never completely relaxed, since there is always a degree of postural tone in all tissues. There may be no conscious awareness of this, but there may be an unconscious desire to retreat from this permanent tension (the death instinct of Freud).

With the advent of prospective imagination, pleasure may be induced by the prospect of relief of tension, and as a result a temporary slight diminution may ensue, although it still persists at a relatively high level. This may prolong and intensify pleasure, and with the alternations of prospective relief and actual imposition of tension the subject may even experience pleasure in painful situations.

(2) Without going into the abstruse question of the derivation of emotional reactions, Dr. Richmond, in "The Adolescent Girl," deals with the difficulty of adjustment of these reactions to the demands of society. A brief survey is undertaken of primitive cults and ceremonies in relation to the change in the girl's life, and a description is given of the physical and mental alterations incident to puberty. She points out that neurosis and delinquency easily arise out of the conflicts of this time, and that it is a matter of some wonder that the 'normal' girl does emerge from the welter of conflicting subjective impulses and objective influences. No attempt is made to discuss the root causes of troubles which arise, but sound advice is given to parents and teachers as to the upbringing of the adolescent, so that they may be alive to the possibilities of disaster and recognise the early signs of trouble, to the end that skilled assistance may be sought before it is too late.

(3) Similarly, Dr. Furfey deals with the preadolescent boy of ten to fourteen years, a period which he designates the gang age, since the child ceases to be individual and discursive in his interests, but concentrates his whole attention on the work of his activities in play. Dr. Furfey regards this phase as one of paramount importance in the normal development of the boy, and therefore one which ought to be supervised most carefully and skilfully. He quotes several case records to illustrate derivations from the normal at this time, and gives good advice as to the proper management of the child at this period of life. As he points out, the average child spends much more time in recreational

than in intellectual activities, and educationists may have neglected the former too much in favour of the latter. It may be advisable for the boy to be allowed a certain freedom to follow his individual bent in recreations, but during the gang age, when individualism is in abeyance, guidance is both wholesome and necessary. R. G. G.

Root Habits and Growth.

Root Development of Field Crops. By Prof. John E. Weaver. (McGraw-Hill Publications in the Agricultural and Botanical Sciences.) Pp. xii+291. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1926.) 15*s*. net.

FROM time immemorial observations and notes have been made on the aerial growth of crop plants under varying conditions of cultivation, and an extensive literature has arisen thereon. On the other hand, the subterranean growth has received little attention, and accurate information as to the relation between shoot and root growth is remarkably meagre. During recent years a few investigations have attempted to remedy this, the most notable contributions being those of Howard in India, and Prof. Weaver and other workers in America. The mechanical difficulties of root investigations *in situ* are such that satisfactory work can only be done where the soil and subsoil are of such a nature as to permit excavation without undue expenditure of time and labour and excessive danger of breaking the roots while their course is being traced. During the last twelve years Prof. Weaver has extensively developed the technique of root excavation by means of systems of trenches, and the volume under review aims at presenting the main American results which have been set forth in detail elsewhere.

The preliminary chapters deal briefly with soil characteristics as correlated with plant growth, and an excellent epitome is given of root structure and development, an elementary aspect of matters which is seldom lucidly explained. From the general point of view, one of the most important sections is that dealing with root habits in relation to crop production. Root growth is often extremely rapid, being so much as ½ inch per day in grasses and 2-2½ inches per day in maize, the total root development being extraordinarily great as compared with the top growth, especially in the early stages. The ratio between the dry weight of shoot and root is often used as a standard of comparison between different plants, but scarcely represents the truth. The real measure of the functioning of a root lies in its absorbing surface, and a very finely branched root has a much greater surface and is far more active in working than a thick, heavy root with few branches.

Weaver opposes the idea, often stated in standard text-books, that crop plants in general are shallow-rooted and that only the top 6 or 8 inches of soil are suitable for growth. A consideration of the conditions under which root investigations have been carried out in various places, however, would lead one to suppose that the nature of the subsoil must play a most important part with regard to root penetration and the absorption of water and nutrients. In deep, easily worked soils and subsoils, such as apparently have been investigated in Nebraska, most crops are able to penetrate well, to develop an extensive root system, and so to commandeer larger stores of deep-seated water and food supplies. In other areas, where a comparatively shallow soil overlies a heavy intractable subsoil, many crops are unable to penetrate far and so gain a character for being shallow-rooted, while a few are able to go rather deeper in spite of the subsoil, and are therefore considered to be inherently deep-rooted. Further work under varying soil conditions will be needed to clear up many of the debatable points raised in the present volume. In humid regions the unproductiveness of the subsoil is recognised, whereas in arid regions this is not so. Greater root development occurs where plant food is plentiful, and this has an important relation to agricultural practice, influencing the depths of manuring, the type of fertiliser used, and the depth of ploughing, according to the crop grown. Tillage methods, as such, may not influence root habit directly, the changes in growth induced by tillering being really in response to differences brought about in the physical and chemical conditions of the soil and subsoil. Varying rooting habits may be turned to commercial advantage, for by growing mixed crops, which tap different soil layers for their water and nutrients, an increased total yield may be obtained. The reason that some weeds are more detrimental to certain crops than others may be because they absorb water and nutrients from the same level as the cultivated plants.

The root habits of native plants afford a useful indication as to soil conditions, and give some guide as to the crop plants that are most likely to succeed. This is specially the case in areas where the water content of the soil is the chief limiting factor to growth, the prevalence of scanty, short vegetation indicating conditions that are unfavourable or even hazardous for crop production. The detailed investigations on the root growth of individual crops not only bring out clearly the difference between one crop and another, but also the variation induced by different methods of cultivation, such as by spring and autumn sowing in wheat. In barley and sugar-beet, particularly, root penetration is much affected by the type of subsoil, as over a dry subsoil a mass of roots is formed in the

surface soil, whereas deep penetration is achieved under other conditions.

An outstanding feature of these investigations is the care and accuracy with which the illustrations have been prepared. Photographs and ordinary sketches proved unsatisfactory in field work, and a method has been evolved whereby each root, as it is traced, is mapped into position on a vertical scale, horizontal maps also being made for certain plants, such as pumpkins, maize or cacti, in which the roots spread widely. A description is given of the method of excavation which has proved so remarkably successful on the type of soil dealt with, and a good bibliography rounds off a volume which fills a definite gap in the annals of agricultural botany and suggests many starting-points for further investigations. Our Bookshelf.

Animals of Land and Sea. By Austin H. Clark. (Library of Modern Sciences.) Pp. xxxiv+276. (New York: D. Van Nostrand Co.; London: Chapman and Hall, Ltd., 1925.) 15*s.* net.

THIS is a good book, but misses being a very good book. It is full of interesting facts, but they are not always well arranged. Mr. Clark's knowledge is extensive and often peculiar, but he has not digested it well: too many of the chapters read like the outpourings of a notebook, not free from unnecessary repetition. Finally, the numerous figures are so dispersed through the book that they can scarcely be said to illustrate the text: thus, opening at random, one finds thirty-four drawings of "biting and parasitic flies, and some maggots and pupae of flies" facing a page that deals with flying-fish. Biting flies were discussed some hundred pages earlier, but there was in the text no reference to these figures; for any further explanation of them one must hark back to the list of text-figures. Possibly the publishers are responsible for this lack of co-operation, for it is a too common fault in popular books written to order. None the less, the authors are to blame, and it is surprising to find a man of Mr. Clark's vigorous personality permitting this indignity.

Towards the end of the book the method improves. The chapter on animal flight is on the whole excellent: it works out certain ideas and subordinates the facts and observations—many of them original—to the main arguments. Yet even here some of the cargo might have been jettisoned with advantage. The chapters on "The Basis of Life in the Sea," "The Intermediate Foods of the Sea," and "The Ocean and the Land"—a contrast between their inhabitants—also puts the facts in a novel light that may reveal points of interest even to those who know them already, and may suggest fresh lines of inquiry. We are acquainted, in a sort of a way, with hundreds of facts that we do not realise; we must fit them into a scheme and see their mutual relations before our acquaintanceship matures into knowledge. It is because Mr. Clark has acted increasingly on this principle that his later chapters are more effective than his earlier. The penultimate chapter—"Life's Borderlands"—which brings together the extremes of temperature, pressure, and the like, under which life can exist, is remarkably interesting.

To write a book of this kind in such a way as to attract a large public is no easy task. The entire and not wholly inexplicable ignorance that most otherwise well-educated people display regarding their fellow-creatures, especially the inhabitants of the waters, presents an almost insuperable obstacle to the writer or speaker who wishes to interest the ordinary man in these aspects of life. We hope Mr. Clark will be found to have succeeded, for his aim, prudently kept in the background, is one with which readers of NATURE will sympathise.

Le Relief de la terre: ses origines, ses lois, son évolution; principes nouveaux de géographie physique. Par Paul Soulier. Pp. x+432+3 planches. (Paris: Félix Alcan, 1925.) 30 francs.

THIS interesting, if not very convincing book may be described as a fugue with the hypsographic curve as its principal theme; a hypothetical structural curve derived from it as the answering subject; the geochemical cycle of water, often repeated, as the counter subject; and a final *stretto* in which these and many related episodes are worked up into an all-embracing explanation of terrestrial relief. The author supposes the effects of denudation and deposition never to have taken place, and shows that the hypsographic curve is then transformed into a simple structural curve. He deduces from this that the structural relief of the earth's surface follows the statistical laws of chance, and therefore, ignoring the implications of isostasy, he rejects Wegener's well-known deduction from the hypsographic curve. Erosion has accentuated the upper concavity of the 'original' curve, and the continental plains and shelves have developed on the middle regions of the structural surface by the accumulation of sediments.

A summary of various theories of mountain building is given and all the existing hypotheses are rejected as inadequate. The author then suggests that water passes down through the surface rocks to an underlying "active orogenic zone," where it promotes aquo-igneous fusion and a general expansion of the materials there present by a process of hydration. The activities of the orogenic zone are made responsible for all the puzzling phenomena of vulcanism, compression, and tension, and for the surface relief of the moon and of Mars as well as of that of the earth. The gradual lowering of the surface of the oceans, due partly to the intensification of relief and partly to the internal absorption of water, leads to the conception of islands developing into continents by coalescence and the uplifting of peripheral mountain systems.

M. Soulier's theory of the earth is not likely to win acceptance, for it runs counter to the modern trend of geophysics. In particular it ignores the effects of radioactivity, and introduces instead a hydrothermal process that seems quite incompetent to produce the results ascribed to it. Nevertheless, the book is original in method and stimulating in thought, and it certainly deserves to be read by those interested in the evolution of the earth's surface features.

Geographie der Moose. Von Prof. Dr. Th. Herzog. Pp. xi+439+8 Tafeln. (Jena: Gustav Fischer, 1926.) 27 gold marks.

While many writers have published works on the anatomy and taxonomy of mosses, Prof. Th. Herzog has struck out on a new line in his recently published volume and given an account of their geographical distribution together with that of the Hepaticæ. He has done for the mosses what Dr. H. Christ did for the ferns in his "Geographie der Farne." Unlike the older writers on plant distribution, he does not give his results in statistical tables but follows the examples of Prof. E. Warming in his "Oecology of Plants," and in the first 74 pages gives an interesting account of the factors, both internal and external, which influence the choice of a habitat, and distinguishes between distribution by spores and by asexual vegetative means. By this method it becomes easy to realise why some species have a wide range while others are confined to a restricted area.

The section dealing with the substratum upon which mosses grow is of special interest and contains lists of species which are confined to either acid, neutral or basic rocks, or to two of them, or (like *Brachythecium rutabulum*) will thrive equally well on any of the three. The epiphytic species are also dealt with in this section. This is followed by 136 pages, in which the distribution of the various families is discussed in detail.

The third section deals in a similar way with the geographical regions and gives numerous examples of the species characteristic of them. A few maps are inserted; that on p. 214 shows clearly the parallelism in distribution in widely separated areas of Gigaspermum and the genus Callitris belonging to the Cupressineæ, namely, north-west Africa, South Africa, and Australia. This Herzog terms "Disjunktionen." The book, which concludes with a classified bibliography and two indexes, one geographical, the other of genera and species, is illustrated with 151 text figures and 8 plates, Fig. 70 showing the various forms of thallus which occur in Aneura. The work should form a stimulating contribution to the literature of bryology.

C. H. W.

The Relation of Nature to Man in Aboriginal America. By Prof. Clark Wissler. Pp. xx+248. (New York and London: Oxford University Press, 1926.) 16*s.* net.

In the text of this volume Dr. Clark Wissler follows closely a course of lectures at the Wagner Free Institute of Science, Philadelphia, which he delivered under the Richard Westbrook Free Lectureship Foundation. It is an admirably lucid exposition of the method of attacking anthropological problems by the study of distribution, and as such it is deserving of careful attention apart from the application of that method to the specific problems of aboriginal America to which the earlier chapters lead. The subjects reviewed are samples of the material culture, segregated distribution, social traits and somatic traits, and finally distribution form and its meaning.

The method is one of special importance in the study of American culture, where indeed there is a peculiarly favourable field for its employment. Its application to the somatic problem is especially instructive in view of the conclusion generally held by American anthropologists as to the homogeneity of the aboriginal population, notwithstanding differences such as that found in head-form. On the ecological side of the inquiry, Dr. Wissler's conclusion is that there is good ground for suspecting that the principle of concentric distribution is an ecological phenomenon universal to the more specialised form of plant and animal life, including man. Dr. Wissler's book is a most valuable and stimulating contribution to the method of anthropological study, but why will he, in common with many other scientific writers, especially in the United States, treat the words *fauna* and *flora* as if they were feminine singular nouns and endow them with an entirely superfluous plural in *æ*?

The Pedigree of the Human Race. By Prof. Harris Hawthorne Wilder. Pp. xiv+368. (New York: Henry Holt and Co., 1926.) 3.25 dollars.

In spite of its title, Prof. Wilder's book refers to the races of mankind only in the last chapter. It is a compilation of a great deal of interesting information relating to the comparative anatomy of the Primates. But it scarcely fulfils the expectation the title suggests, for there is relatively little serious discussion of the pedigree. In a work dealing with man's ancestry, it is rather surprising to find no mention of Propliopithecus, perhaps the most interesting link in the chain, and an absence of reference to the leading works on the subject of the book.

The classification of the Primates is peculiar. The Tarsiidæ are included in the sub-order Anthropoidea. Though much might be urged in excuse of such a course, it can only create unnecessary confusion; and the student who critically studies the differential tables on pp. 25 and 26 will certainly be at a loss to discover why Tarsius is put under the heading Anthropoidea and not under Lemuroidea, seeing that it is cited as exceptional in respect of every feature enumerated and in most of these agrees with the Lemuroidea. Then again, alongside this ultra-modern treatment of Tarsius the antiquated idea with regard to Chiromys is retained. This specialised member of the Indrisinæ is removed from its own family and a special sub-order is made for its reception.

The book contains a large series of useful illustrations.

The Annual Register: a Review of Public Events at Home and Abroad for the Year 1925. Edited by Dr. M. Epstein. Pp. xiv+330+180. (London: Longmans, Green and Co., Ltd., 1926.) 30*s.* net.

This invaluable work of reference again gives a complete survey of the world's history during the past year in a small compass and a readable form. The customary arrangement is followed, of considerable sections devoted to Great Britain and the Empire, with smaller sections on other States. There are also surveys of the literature, science, art, drama and finance of the year, and a record of events. Appendices give the full text of the Locarno Treaties, the Irish Boundary Agreement, the Irish Bill 1925, and the Russo-Japanese Treaty. The work has now reached its 167th annual issue.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Microstructure of Mercury.

IN the course of investigations on dental alloys and amalgams, which we have carried out at the National Physical Laboratory on behalf of the Dental Investigation Committee, Department of Scientific and Industrial Research, we have thought it necessary, for the full study of the constitution of the amalgams, to undertake their microscopic examination. As mercury, and the amalgams rich in mercury, must be completely solidified for this purpose, it has been necessary to devise means for the preparation, etching, and photo-micrography of specimens at very low temperatures. Most of the work has been done by means of a paste of carbon dioxide snow and acetone.

FIG. 1.—Microstructure of pure mercury. Magnification × 100.

Surfaces suitable for microscopic study have been prepared by allowing the metal to solidify in contact with glass, and such surfaces have been successfully etched by electrolysis in hydrochloric acid (sp. gr. 1·12 at 15° C.). It has also proved possible to polish the frozen specimens, but so far it has *not* been found possible to etch surfaces prepared in that way.

Special devices have been used for keeping the lenses of the microscope, etc., free from deposits of frost during examination and photography. Fig. 1 is a reproduction of a photograph showing the typical microstructure of solid mercury under a magnification of 100 diameters; we believe that this is the first time that such a structure has been recorded.

The Damping of Pendulous Jets.

IN a previous letter to NATURE (April 11, 1925, p. 530) the behaviour of liquid jets from a moving source was discussed theoretically, and supporting experimental data were presented. Dr. Julius Hartmann reviewed the subject in the issue of NATURE of June 6, 1925, p. 872, and arrived at confirmatory conclusions, though adopting a different mode of attack and manner of statement. Both of these communications treated the particles constituting the jet as though in free flight. The possibility of their being subject to viscous constraints while in flight was alluded to in the former paper, but Dr. Hartmann detected no such damping effects under his conditions of observation. Lately, Mr. Walter Thompson and I have examined the damping effect, and as the conclusions admit of concise statement they are presented herewith.

To recall the experimental conditions it may be stated that we have under consideration a jet of liquid issuing vertically downward, and that the container is subject to a linear, horizontal, oscillatory motion, and, in a particular case, a simple harmonic motion. The problem is the description of the horizontal motion of the jet at lower levels. It may be very simply shown that if the particles of the jet are acted upon during their fall by no force except gravity, and if the time of fall to the level considered is T, then the displacement of the jet from an arbitrary initial position will be $X = s + T\,ds/dt$. In this equation s represents the displacement of the container from its initial position at the instant of release of the particle observed. If damping forces, such as might be supplied by viscosity, are present, the particle, and hence the jet, will fall short of the displacement X defined above.

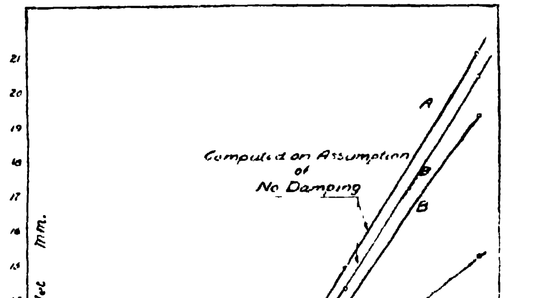

FIG. 1.—Effects of frequency and viscosity in diminishing the range of oscillation of jets. B curves are for a viscosity of 0·75 poises, A for 6·4 poises. Times of fall, about 0·75 seconds.

We experimented with six different oil mixtures, varying in viscosity from 0·75 to 6·45 poises, but otherwise physically similar. The specimen studied

was delivered from a cylindrical glass nozzle in the bottom of a container which executed horizontal simple harmonic motion of adjustable amplitude and period. Following the reasoning of the free-fall equation given above, one may readily compute the jet amplitudes to be expected, in the absence of damping, for any particular applied simple harmonic motion. Measuring jet amplitudes by a variety of methods, including photographic, we have compared actual with predicted values in several hundred cases.

It is learned that with low frequencies (one cycle per second or less) all of these liquids show amplitudes agreeing with the simple no-damping predictions, but that all of them, even the least viscous, show diminished amplitudes when the frequency is greater than two cycles per second. The more viscous the liquid the lower is the frequency at which this damping first appears. After its first appearance, damping always increases with increasing frequency, but at a slower rate with less viscous liquids. The variation of the damping threshold with viscosity is such as to indicate that only a liquid of zero viscosity would be entirely free from damping at high frequencies. Damping is very nearly independent of amplitude, though a slight increase with increasing amplitude may be observed.

The accompanying diagram (Fig. 1) illustrates the effects of both viscosity and frequency on the jet amplitudes.

These findings are of interest in connexion with the suggested use of recorded jet motions for the absolute measurement of seismic or other accelerations. The proposals are discussed in the communications to NATURE referred to above. It now appears impracticable to arrange a jet of any liquid which shall be sensibly undamped at frequencies so high as four cycles per second, and yet be viscous enough to fall unbroken for so long as half a second. A succession of falling solid spheres would seem to offer better opportunities for the development of the suggested method.

PAUL KIRKPATRICK.

Another Patagonian *Lusus Naturæ*.

RECENTLY I was interested to hear, from a friend, of the discovery in Patagonia of a representation of a human head sculptured in stone, and, at his request, the finder kindly allowed me to have it for examination.

I expected that it would be more or less of the same type as the rudely fashioned head[1] found by Prof. Franz Kuhn at Punta Arenas in the south of Chile, and now in the Natural History Museum of Buenos Aires; but when the object arrived it was at once evident that, although it bears a remarkable resemblance to a human head with definite features, it owes nothing of its form to human agency, and is, in fact, a strange freak of Nature

It was found, lying on the surface of the ground, in Tierra del Fuego, exactly where I do not know, and consists of a nodular piece of rock, weighing 1750 grams, and measuring 155 mm., 115 mm., and 75 mm. in its greatest length, breadth, and thickness respectively (Fig. 1). The surface is covered with a greyish patina, except where rubbed off on the projecting parts, which are of a dark, metallic grey colour. In appearance the stone resembles basalt, and is very probably an altered rhyolitic rock, but its nature cannot be accurately determined without submitting a section to examination under the petrological microscope. At one end there is an ancient fracture, and when the stone is set up on this

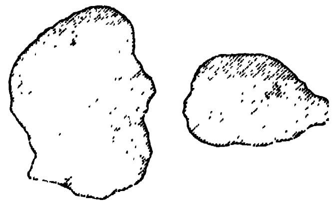

FIG. 1.—Vertical and horizontal profiles of the stone: scale ⅓.

as a base, it has the appearance of a bearded head, as may be seen from the photograph (Fig. 2). The fact of the fracture occurring at what seems to be the neck serves to strengthen the illusion, giving the impression that it is a head which has been broken from a statue

FIG. 2.—One side of the stone, from an untouched photograph: scale nearly ⅓.

South America has gained an unenviable notoriety as the source of periodical announcements of sensational palæontological and archæological discoveries, which, when investigated, generally prove to have no foundation in fact. The affair of Paso Ibáñez, in which a lump of sandstone was put forward as a fossil human skull of Tertiary age,[2] will yet be fresh in the memories of many, and the purpose of this note is to prevent any misconceptions as to the true nature of the object described, should it ever figure in the daily Press either as yet another 'proof' of the existence of Tertiary man in South America, or as a remarkable example of stone carving by the prehistoric inhabitants of Patagonia.

Dwi-Manganese in Native Platinum.

CHEMICAL EXAMINATION.—Native platinum was long ago the subject of investigation and the search for elements not yet discovered. Kern, in the year 1877 (*Chem. News*, **36**, 1877, and **37**, 1878), A. Guyar

[1] This is figured by R. Hauthal, "Zwei bemerkenswerke Funde im südlichen Patagonien" (Congrès International des Américanistes. *Compte rendu* de la XXIe Session, deuxième partie, tenue à Goteborg en 1924, Fig. 6a, p. 518), Göteborg, 1925.

[2] The story of this extraordinary 'discovery' has been told by J. Imbelloni, "Nota sobre los supuestos descubrimientos del doctor J. G. Wolff en Patagonia" (*Revista de la Universidad de Buenos Aires*, vol. 51, pp. 39-51), Buenos Aires, 1923, and "L'uomo terziario fossile della Patagonia e la sua veridica istoria" (*Revista mensile del Touring Club Italiano, Le Vie d' Italia e dell' America Latina*), Milan, 1924

(*Chem. News*, **40**, 59, 1879), Kurtz (*Trans. Amer. Inst. Min. Eng.*, **33**, 347, 1903), A. French (*Chem. News*, **104**, 283, 1911) and many others claimed to have found new elements in native platinum. These 'discoveries,' however, have not been confirmed. In 1925 W Noddak, I. Tacke and O. Berg (*Die Naturwissenschaften*, No. 26, pp. 167-174, 1925) published a paper stating that they found in native platinum from the Gorablogodatski region, Ural, an element of atomic number 75. The quantity of the discovered substance was, however, so small (about 1 mgm.) that it was not possible to carry out conclusive experiments.

We have tested the native platinum systematically for the presence in it of dwi-manganese (No. 75). The platinum (mixed) was treated chemically, and the final products were investigated Röntgenographically. Dwi-manganese would have been easily detected if it were present in the native platinum in quantities pointed out by Dr. Noddak, or even 10 or 100 times less than that. As a matter of fact, the Röntgenographs obtained prove with certainty the absence of dwi-manganese in native platinum in a quantity exceeding 0 0003 per cent.

Our investigation thus settles the question about the presence of manganese analogues in native platinum in the negative sense. It is also very likely that eka-manganese, a closer analogue of manganese and a rarer element in the earth's crust, is not present in native platinum. Druce (*Chem. News*, **131**, 273, 1925) and Heyrovský (NATURE, November 28, 1925, p 782) seem to have chosen a more trustworthy way, assuming that dwi-manganese is associated with manganese and not with platinum.

RÖNTGENOGRAPHICAL EXAMINATION.—The investigation of the spectra was carried out either with Siegbahn's vacuum spectograph or with Muller's spectrograph with Hadding's tube In both cases the Röntgenographs were obtained with calcite crystal by the method of a fixed crystal. For the determination of the wave lengths of unknown lines, the lines $K\alpha_1Cu$, $K\beta_1Cu$ and $L\alpha_1W$ were chosen for reference lines (the substance under investigation mixed with about 5 per cent. tungsten was deposited on the anticathode of copper). The wave-lengths of the unknown lines were calculated from the following formula:

$$Ctg\ (\theta_2 - \theta_1) \quad \frac{a_{23}}{a_{13}} \; \frac{\sin(\theta_1 - \theta_3)}{\sin(\theta_2 - \theta_3)\sin(\theta_1 - \theta_2)} \quad Ctg\ (\theta_1 - \theta_2),$$

where θ_1, θ_2 and θ_3 denote the angles of deflexion for three given lines and a_{1x}, a_{2r}, a_{13} and a_{23} denote the mutual distances between the lines, measured with a comparator.

On Röntgenographs obtained with Müller's spectrograph, the doublet $K\alpha Cu$ was well resolved (the width of the lines was 0·06 mm. with equal breadth of the slit).

The accuracy of measurements of wave-lengths was 0·4 X.U., but no lines were found in the region where the K lines of the element 75 would be expected.

Kaufmann's Experiment and the Spinning Electron.

IN a paper in a recent number of the *Zeitschr. für Physik*, Wentzel has published a calculation of the X-ray screening constants on the basis of the spinning electron. He obtains values of the screening constants which are much larger than those experimentally determined, so raising a difficulty in the way of the acceptance of the spinning electron. Wentzel introduces into the calculations a force $1/c(\mu[vX])$ (μ = magnetic moment of spinning electron, v = velocity, X = electric field) the exact analogy of the force $e[vH]$ on a moving electric charge in a magnetic field.

It can readily be shown that, if this force is accepted as having a real existence, Kaufmann's experiment is conclusive against the spinning electron. In this experiment the moving electrons are subjected to the action of parallel electric and magnetic fields. The deflexions of the electrons due to the actions of the fields are thus perpendicular to one another, and in the case of the spinning electron there will be an additional deflexion due to the force $1/c(\mu[vX])$. This deflexion will be in the same plane as that due to the magnetic field. Then, taking the simple theory of the experiment (as given, for example, in Richardson's "Electron Theory of Matter"), we have for the deflexion in the plane parallel to the condenser plates

$$x_1 = (He + X\mu/c)z'(z' - z_1)$$

the $\pm$ sign being required because of the spatial quantisation of the spinning electron in the magnetic field.

Since now X ncH, in which n is a factor of the order 1/2 in Kaufmann's experiment, and $\mu = 2eh/4\pi m$ or two Bohr magnetons, it can be seen on inserting the values of the constants concerned that the quantity in the first bracket in the expression for the deflexion is approximately equal to $He(1 \pm \frac{1}{2})$. It will thus be seen that, instead of the trace on the photographic plate being a single arc of a parabola, this, for the case of the spinning electron, will consist of arcs of two parabolæ, the x co-ordinates of which are respectively approximately $\frac{1}{2}$ and $\frac{3}{2}$ of those of the arc obtained with the non-spinning electron. Kaufmann's published photographs do not appear to show any sign of this double trace. Hence, provided that the force $1/c(\mu[vX])$ has a real existence, Kaufmann's experiment shows definitely that the free electron cannot possess any spin comparable with that required by Goudsmit and Uhlenbeck's theory. This, of course, applies only to free electrons, and does not preclude the possibility that the electron may possess such a spin when it is a constituent part of an atom.

L. C. JACKSON.

Liver Extracts in the Treatment of Malignant Disease.

THE liver is proportionately very large during early fœtal life when rapid growth is the most prominent factor in the life of the organism. Since the formation of bile has not commenced at this stage of existence, the relatively large size of this organ may be attributed to the probability that it exercises some influence on the growth of the body. This effect would be brought about presumably through the medium of an internal secretion. As malignant disease in its various forms is primarily a manifestation of abnormal cellular growth, I attempted to determine the presence of such an

active principle and to isolate it in a form suitable for therapeutic use.

The work was initiated in the laboratories of the Hamilton General Hospital with the co-operation of Dr. W. J. Deadman. Extracts of fœtal pig livers were used during the earlier stages of the work on animals. Later extracts of both fœtal and adult pig livers were employed in the clinical work. The preparations were first administered to mice in which Marsh tumour tissue had been transplanted, an equal number of transplanted animals being untreated and used as controls It was noted that as compared with the controls the extension of the transplanted tissue was arrested in the mice under treatment, and with repeated injections distant from the site of the tumour, a total necrosis of the transplants occurred. The degeneration of the tumour tissue did not take place in the centre of the mass as normally occurs, but commenced at the periphery of the growth.

The work was afterwards transferred to the McGregor-Mowbray clinic of Hamilton, which has borne the entire expense of the earlier chemical investigation, and under the supervision of which all the clinical research has been carried out. The preparations which were originally employed contained relatively small quantities of the active principle. Recently the co-operation of Profs A. Bruce Macallum and A. A. James, of the Department of Biochemistry of the University of Western Ontario, London, has been enlisted, and they have developed a preparation from beef livers which contains the active principle in a highly concentrated form and can be rapidly and economically prepared. These preparations effect no changes in the blood pressure.

The clinical results to date in those patients who have received the treatment may be summarised as follows: in one patient there was complete disappearance of the tumour mass; in others still under treatment a reduction in the size of the growth has been noted. In every case the progress of the disease has been arrested and the life of the patient prolonged beyond that of the prognosis given before treatment commenced. So far only inoperable and otherwise hopeless cases have been treated No radical claims are advanced for this treatment, but the results obtained clinically have warranted a more extensive investigation which is now being carried out at the University of Western Ontario, London, and the McGregor-Mowbray Clinic, Hamilton.

This preliminary communication is made for the purpose of scientific record.

Kammerer's Alytes.

As I was intimately connected with Dr. Kammerer's visit to England in 1923, and as his specimens were unpacked in my laboratory and examined there before being taken to Cambridge, perhaps I may be allowed to make some comments on Dr. Noble's communication to NATURE of August 7. As to the present condition of the Alytes, about which there has been so much controversy, I know nothing. Dr. Przibram's view that the specimen after its return to Vienna was allowed to fade and macerate and that then a clumsy attempt at 'faked' restoration was made, appears to me probable. But this specimen was demonstrated to a continuous stream of critical observers for a whole afternoon in the Zoological Laboratory at Cambridge by Dr. Kammerer, who removed it from its case and invited examination under a lens. We all saw the spines; it was these and not the colour which convinced us. Dr. Noble may set his mind quite at rest as to the former existence of nuptial asperities.

I possess a print of the photograph which shows them —it is not a question, as Dr. Noble imagines, of two or three spines but of a whole series of minute spines regularly spaced which can be clearly seen in profile along the edge of one of the fingers.

In the attack which he made on Dr. Kammerer at the meeting of the British Association last year, Dr. Noble laid great stress on the peculiar glands characteristic, as he said, of the nuptial pads, indeed, as he then stated, diagnostic of them, whilst the asperities were irrelevant. By his reference to Champy's paper in his present letter it is clear that he has since discovered his mistake. The glands found in these pads are merely the ordinary skin glands hypertrophied under the influence of the sexual hormone as the breeding period approaches. I have compared photographs of the sections through the normal skin of Alytes and through the 'pad.' The skin glands in the latter section are double the size of those in the former.

In conclusion, I may say that when Dr. Kammerer came to my laboratory in 1923 he brought other specimens about the existence of which I was sceptical until I saw them and which struck me as much more wonderful than Alytes. I refer to the large-eyed specimens of Proteus.

I suggest that Dr. Noble and his colleagues, instead of making aspersions on the good faith of a fellow-worker and the credulity of English scientists, would be better employed in endeavouring, as I have done, to repeat Kammerer's experiments, and when they have produced anything half as wonderful as the Proteus their comments will be listened to with more patience. E. W. MACBRIDE.

The Birefringence of Crystalline Carbonates, Nitrates and Sulphates.

IN two very interesting papers (*Proc. Roy. Soc.*, vol. 105, p. 370, and vol. 106, p. 346, 1924) Prof. W. L. Bragg put forward an explanation of the strong birefringence exhibited by the crystalline carbonates and nitrates. Expressed very briefly, his theory is that in the carbonate and nitrate ions the oxygen atoms are situated in one plane around the central carbon or nitrogen atom, as the case may be, and that, as the result of this arrangement and of the mutual influence of the electric doublets induced in the atoms by the field of the light-waves, the refractivity of the group depends to a marked extent on the direction of the light-vector. The refractive indices of the crystal were successfully computed on this basis. The crystalline sulphates are known, on the other hand, to have a very weak birefringence, and the suggestion was made that very probably the oxygen atoms are arranged tetrahedrally round the sulphur atom in the sulphate ion group, thus making it optically isotropic.

Very interesting evidence regarding the birefringence of the nitrate and sulphate ions is furnished by some recent observations on the scattering of light by concentrated acids and their aqueous solutions made in the present writer's laboratory by Mr. S. Venkateswaran. The light scattered by dust-free nitric acid is found to be nearly unpolarised, indicating an extremely large anisotropy for the nitric acid molecule and for the nitrate ion. Concentrated sulphuric acid and its aqueous solutions, on the other hand, polarise the scattered light nearly completely, indicating that the sulphate ion is nearly isotropic optically. We

have thus a striking confirmation of Prof. Bragg's views.

Observations on the scattering of light by concentrated solutions of salts and by organic vapours containing the groups in question have been undertaken. One may venture confidently to predict the results to be expected. C. V. RAMAN.

June 10.

The Reduction of Carbonic Oxide.

EVEN politicians are attracted to this problem and see in it not red but the oils of to-morrow. If peers speculate in futures, why not we plebeian sciencers, who give our lives to such matters, not a princely two days or so? The victim of a pernicious complaint contracted in the service of the British Association in the granitic environment of Aberdeen, pursuing the vicious line of thought which has afflicted me since 1885, I have recently been led to make logical use of my singular views on the course of chemical change and apply them fully to this most remarkable, perhaps *the* most remarkable, of molecules—carbonic oxide. No other molecule has 'taken us in' so long. All my life I have been seeking to fathom its mysterious depths: even now I don't feel in safe soundings.

I have argued, before the Royal Society and at the recent Solvay Conference, that it is not directly oxidisable by oxygen: the potential of the circuit would be too low. Prof. Bone and I are duelling over this issue at the moment: the foils are to be without buttons.

If my line of thought regarding its oxidation be sound—I seem to see signs that the force of facts is beginning to tell in its favour, at the same time that trousers are no longer all built turned up, those who dabble in science being as unable as are ordinary mortals to follow one fashion for ever—the reverse operation, the direct reduction of the gas by hydrogen, should be equally impossible, catalyst or no catalyst. Some adjuvant action must intervene to effect reduction if the carbonic oxide-hydrogen potential be below the oxygen-hydrogen potential. F. Fischer's suggestion that the process is an indirect one is, therefore, of special interest. The modifications of the fundamental equation given by Messrs. Elvin and Nash (NATURE, July 31, p. 154) are no more likely than that equation is as an expression of the character of the chemical change. Metallic carbonyls are perhaps concerned in the transformations.

Operation of Fog-Signals from a Distance.

IN the issue of NATURE for July 10, p. 58, reference is made to an installation for the operation of fog-signals from a distance. I wish to direct attention to two misstatements. The apparatus is not automatic in the strict sense of the term, as it requires to be started and stopped by human agency. The statement "These guns are the only automatic signals at present in use" may apply to the Clyde, but there are two lighthouses in the port of Dublin which are equipped with automatic fog-signalling apparatus, and these have been in operation there for almost two years. The system in Dublin depends on the interruption of a beam of light by fog. The light beam traverses the channel in an oblique direction over a distance of about half a mile, and the apparatus upon which the light acts is so arranged as to respond when the visibility falls to a dangerous degree. These lighthouses in Dublin were undoubtedly the first completely automatic lighthouses to be in operation. JOHN J. DOWLING.

University College,
Dublin, July 13.

I REGRET to have to confess ignorance about the two lighthouses in Dublin Bay. It would be of interest to know whether smoke from a passing steamer affecting the beam of light causes the 'guns' to act. I am well aware that engineers have often discussed the proper use of the word 'automatic.' Automatic telephony, for example, is not automatic in the strict sense of the term. It would take too long to discuss this fully, but personally I object to 'semi-automatic.'

THE WRITER OF THE NOTE.

Scientific Neglect of the Mas d'Azil.

L'ÉTAT d'abandon que l'illustre écrivain M. Wells signale pour la caverne du Mas d'Azil est réel et fort regrettable, bien que les conséquences en soient probablement moins graves qu'il ne pense. Elle appartient à l'état, mais la commune en a l'usage de temps immémorial. Le cantonnier chargé de l'entretien de la route départementale qui la traverse en est le gardien officiel; c'est lui qui fait visiter les galeries obscures, plus intéressantes par le pittoresque que pour la science préhistorique, bien que de rares dessins pariétaux s'y rencontrent, et, deci-delà, quelques menus vestiges de fréquentation humaine. Sur la rive droite, le point important était la salle du Foyer et sa galerie inférieur. La salle du Foyer a été fouillée depuis longtemps dans sa totalité par Piette, Ladavèze, Maury, etc, et en dernier lieu (1901–1902) par moi-même. Je doute qu'elle contienne actuellement autre chose que les déblais de ces fouilles, sauf son couloir inférieur, où existent quelques peintures étudiées par le Comte Bégouen et moi. Les couches archéologiques peu épaisses qui y subsistent vers le fond sont sans doute l'objet des grattages dont M Wells nous entretient. Plus grave est le bouleversement réalisé l'année dernière dans cette région de la grotte par la municipalité pour y installer un théâtre. Mais je ne crois pas que les lieux de la caverne contenant encore du gisement, placés sur l'autre rive, aient été touchés récemment: une épaisse couche de pierrailles et de terre poudreuse les défend bien. H. BREUIL.

Preservation of Mammalian Spermatozoa.

IT may be of interest that experiments on the preservation 'in vitro' of mammalian spermatozoa show some prospect of successful application to the transport of semen to a distance; a problem of considerable importance in animal husbandry. Spermatozoa from a rabbit were sent by post from Cambridge to the Animal Breeding Research Department, University of Edinburgh. From 5 does inseminated, 46-49 hours after despatch, 3 produced litters of 8, 11, and 2 respectively. One doe died without diagnosis of pregnancy and one proved infertile.

Although the technique excludes the practical application of this particular method to the domesticated animals, further experiments are in progress, and it is hoped that these difficulties will be overcome.

The Production of Single Crystals of Metals and some of their Properties.[1]

By Prof. H. C. H. CARPENTER, F.R.S.

THE problem of preparing a piece of metal in the form of a single crystal may be approached in one of two ways. As ordinarily prepared, metals and alloys consist of a large number of small crystals the size of which varies in the great majority of cases from about 100,000 to several million in a cubic inch. These result from the fact that when the metal or alloy freezes, crystallisation takes place at a large number of centres and the crystals grow until they meet one another. The boundaries, therefore, are produced by the meeting of these crystals and vary very much in shape. The net result is rather similar to that of a jig-saw puzzle, for the crystals are oriented quite at haphazard. The shapes and sizes of these crystals may be altered by working and heat-treatment, and the precise rearrangement may go so far as to result in the birth of new crystals, but the net result is always an aggregate of comparatively small crystals.

The properties of metals and alloys are the properties of these small crystals, and are due to two factors—(*a*) the crystal itself, and (*b*) the crystal boundary. In the crystal itself the atoms are arranged in a particular pattern corresponding to the symmetry of the metal. At the boundary, on the other hand, this condition does not obtain. For example, where two crystals are in contact atoms meet in two different directions, while at the place where three crystals touch, atoms meet in three different directions, and so on. It has been known for some time that the crystal boundary is stronger than the metal crystal, in the sense that normally when a metal is fractured it breaks through the crystal and not along the boundary, and the fracture of a metal test-piece is the summation of a large number of fractures running through small crystals. Hitherto it has been impossible, except in a very few isolated cases, to determine the properties of a metal crystal apart from those of the crystal boundary. The great and indeed fundamental interest of the problem of preparing a piece of metal in the form of a single crystal, therefore, is that its solution would enable the properties of the metal crystal to be determined.

SINGLE CRYSTALS FORMED DIRECT FROM THE LIQUID.

Evidence has been in existence for some time that, provided that the right conditions obtain, very large crystals can be grown from the liquid. The famous Tschernoff crystal dates back to about 1880. It was a large iron crystal, which he noticed in the 'riser' (head) of an ingot at the Vickers' works in Sheffield, and was upwards of 6 in. in length. Its shape was peculiar, and was what is called a 'crystal skeleton'—*i.e.* it had grown along the crystallographic axes to a greater extent than the filling-in process had occurred, and the net result was something which looked very like the branch of a pine-tree. Other instances of the accidental occurrence of large crystals have been noticed by Osmond and Cartaud, Moellendorff and Czochralski.

So far as I have been able to discover, the problem of preparing a single crystal direct from the liquid was first solved by Czochralski in 1918. He prepared long thin threads of crystals by drawing out a rod at a particular rate from the molten metal. As the rod was withdrawn the metal solidified and the resulting wire (0·5 mm. diameter) was found to consist of one crystal. Success was thus achieved with tin, lead, and antimony. Later Gomperz improved the technique of Czochralski's method. He used a silica rod on which to deposit the crystal growing from the melt and surrounded this with a neutral gas.

Quite recently (1923 and 1925) P. W. Bridgman has prepared much larger single crystals by melting the metal in a tube tapered at one end to a point and lowered through the furnace at a given rate. He found that if the lowering is at a speed less than the velocity of crystallisation and slow enough for the heat of solidification to be dissipated by conduction, then the metal will usually crystallise as one grain, provided that only one nucleus started at the bottom of the tube. In this way he prepared crystals of antimony, bismuth, cadmium, tellurium, tin, and zinc. It is particularly interesting to notice that this method also holds for metals having a polymorphic transition point (tin and antimony).

The melting was carried out *in vacuo*, and great stress is laid on the importance of freedom from dirt as an essential condition of success. At some little distance from the bottom the tube was constricted to a capillary, 0·1 mm. in diameter. It was found that one orientation of the crystals is usually more favourable for growth than others, so that even if crystallisation starts from more than one centre at the bottom, that crystal will eventually win through the capillary which is most favourably situated. Bridgman found that the most favourable orientation is, in almost all cases, when the plane of easiest cleavage or slip is parallel to the axis of the casting. In this way single crystal rods up to a diameter of 2·2 cm. were prepared. The same device was adopted by Obreimow and Schubnikow.

Valuable work on the single crystal wires produced by Czochralski's method and their distortion by mechanical stress has been carried out by Polanyi, Schmid, and Schouborn, while Bridgman has determined a number of physical properties of his single crystals of metals, which were purposely chosen because they did not possess the highest symmetry and therefore might be expected to give different values in different directions. This expectation was fulfilled.

SINGLE CRYSTAL TEST-PIECES FROM PRE-EXISTING CRYSTALS.

Here, again, a study of the literature showed it to contain a number of observations which indicated that, provided that the right conditions were obtained, success might be achieved in this direction, although the chances did not appear so good as that of preparing

[1] From the sixteenth May Lecture to the Institute of Metals, delivered on May 19.

a single crystal from the melt. Sauveur was, I think, the first investigator to show that, by carefully straining and afterwards heating metals, crystals of a much larger size than the normal could be produced, and stated that there was a critical stress which produced the largest crystals. Afterwards Ruder, Chappell, Jeffries, and Hanson showed that if a metal is locally deformed and then heated, exceptionally large crystals form at some distance from the point at which stress is the severest. If a tapered test-piece was used a 'strain gradient' was obtained, and it was found that the largest crystals always formed within the strained region, but farther from the area of greatest strain the higher the temperature. Seligman and Williams, working in my laboratory, stretched aluminium sheet, which had been previously heated, to various degrees, and found on heating that, up to a certain point, a small deformation had no effect. Beyond this, however, large crystals were formed, and as the deformation was further increased the crystal size was diminished. The crystals produced by these methods were very large compared with those in the original metal, some of them being 0·5 in. long.

In recent years wires have been produced, originally by accident, both of tungsten and molybdenum, in which crystals occupy the entire cross-section of the wire. This is done by drawing the metal through dies at a certain rate and temperature. Sykes, experimenting on molybdenum wire, obtained crystals 0·5 in. long, with an average diameter of 0·013 in.

Experiments on the production of single aluminium crystals were begun several years ago by Miss C. F. Elam, my research assistant, and myself. For many months we studied the structural changes produced in a crystal aggregate by deformation followed by heat, which may be summarised as follows: The first effects of strain are revealed by the presence of slip-bands, and in some cases of twin crystals. The former are completely, and the latter to some extent, removed by heating. No change is observed in the shape of the crystals. Somewhat greater deformation, however, followed by heat, produced actual crystal growth, and at this stage the boundaries of the crystals became active. This activity is shown in the capacity of the growing crystal to push forward its boundaries in certain directions, thus invading other crystals, upon which it imposes its orientation. A still greater deformation produces a change which appears to take place exclusively in the boundaries of the deformed crystals. It is here that new crystals are born, possessing a different orientation and a much smaller size. Accordingly, in this third stage there is a refining of the crystal structure. From the point of view, therefore, of producing large crystals from an aggregate of small ones, the intermediate degree of strain, just referred to, is the important one.

The increase in crystal size could be clearly followed in our experiments with an alloy of tin containing a little antimony, where the actual movement of the crystal boundary was observed and photographed. Our experiments further showed that in the absence of a change of phase neither crystal growth nor recrystallisation will take place in a metal unless it has been plastically deformed and afterwards heated to a certain minimum temperature for a certain minimum time. They also showed that there is no gradual increase in size from the original crystals up to the largest, but that the latter appear to form directly from them. It is clear therefore that, in the production of large metal crystals, the adjustment between mechanical strain and the temperature of heating is extremely important.

This point can be clearly illustrated in the case of the metal aluminium. Test-pieces, after preliminary heat-treatment to remove work hardness and render the crystals so far as possible equiaxed, were subjected to varying degrees of strain. After this they were all heated to 550° C. for 6 hours. Finally, they were etched in a 10 per cent. solution of caustic soda. Below the minimum strain required for growth, the crystal size remains unaltered. At the critical strain large crystals suddenly appear. Above this the size diminishes in proportion as the strain increases.

PRODUCTION OF SINGLE CRYSTALS IN SHEETS.

By this time we were ready to approach the problem itself, and our first experiments aimed at converting the crystals in the parallel portion of a test-piece 4·0 in. × 1·0 in. × 0·125 in. of aluminium into a single crystal. Calculation showed that the total number of crystals contained in the parallel portion of the test-piece was about 1,687,000.

After many months of work success was achieved in the following way: The test-piece must, in the first place, be accurately machined along the parallel portion. In order to convert this into a single crystal three treatments are necessary: the first thermal, the second mechanical, the third thermal. The first treatment is necessary to soften the metal completely and produce new equiaxed crystals of so far as possible uniform size, the average diameter being $\frac{1}{150}$ in. The second consists in straining these crystals to the required amount, and the third in heating the strained crystals to the requisite temperature, so that the potentiality of growth conferred by strain could be brought fully into operation.

The most suitable temperature of the first heating was found to be 550° C., and the time 6 hours. The precise degree of strain for the aluminium used was an elongation of 1·6 per cent. on 3 in. produced by a stress of 2·4 tons per sq. in. The final heat-treatment was begun at 450° C., and the temperature raised at about 25° C. per day up to 550° C. It was then brought finally up to 600° C. for one hour, in order to complete the absorption of small crystals on the surface, which persistently remained at lower temperatures. On an average, one test-piece in four is converted into a single crystal in this way. The boundary at each end extends in the form of an irregular line into the wide head of the test-piece. The time required for the single crystal to grow in this way is therefore about 100 hours.

The conditions laid down by us for the production of a single crystal were that every crystal in the complex should be strained a certain small amount, and that one of them should be strained rather more than all the rest. We were originally disposed to think that the crystal which grew and absorbed all the others was the one most highly energised by strain. Later investigations with X-ray analysis, however, have shown that

single crystals produced in this way are free from strain, and we have accordingly modified our view and consider that the most highly strained crystal deposits a nucleus free from strain upon which all the other crystals ultimately align themselves, thus producing an unstrained single crystal.

PRODUCTION OF SINGLE CRYSTALS IN BARS.

We next proceeded to apply these methods to the production of single crystals in round bars. We found that, provided that the same conditions as to accuracy of machining, correct crystal size, degree of straining, and final heat-treatment were maintained, single crystals could also be produced in round-bar test-pieces, both in diameters of 0·564 in. and 0·798 in. Single crystal test-pieces 9 in. long and 0·564 in. in diameter have been prepared in this way.

Deformation of these test-pieces under tensile stress is very remarkable. On one hand, the 'normal' bar, consisting of small crystals, drew down with a roughening of the surface, a cup and cone fracture, and the maintenance of a circular cross-section throughout. On the other hand, when a single crystal was pulled in this way it produced an ellipse. As the test proceeded the ellipse became narrower and narrower in one diameter, while the other diameter remained nearly constant. Presently a point was reached when a characteristic lens-shaped figure was formed. As the bar pulled apart this became smaller and smaller. Eventually fracture took place at each side and ultimately in the middle.

The final result was that the fractured surface of each half of the test-piece was a very acute ellipse or wedge, the metal being grooved in each case. Characteristic flow lines also made their appearance on the test-pieces, corresponding to the slipping of the metal in this remarkable and quite novel way. They may be called 'glide-ellipses' Here, again, the properties varied considerably in different specimens, the tenacities ranging from 3·0 to 4·0 tons per sq. in. and the elongation from 57 to 85 per cent. In some of these experiments the volume of the single crystal exceeded 2 cu. in., which means that about 7,000,000 crystals had coalesced in their formation.

It has not been found possible to produce single crystal test-pieces of square bars. Owing to the shape, these fail to strain uniformly, and, on heating, crystals grow from the four corners and meet in a line in the middle of the four sides. Some of the crystals were from 2 in. to 3 in. long and were visible on two adjacent sides. Remarkable effects were obtained on breaking them. In some places the corners became rounded, while in others they were narrowed to a ridge of almost knife-edge thickness. The whole bar became very much twisted and distorted.

ANALYSIS OF THE DISTORTION OF SINGLE CRYSTAL BARS.

The distortions of the single crystal test-pieces produced both in sheet and bar forms were very remarkable, and clearly suggested that the crystal axes were not oriented in the same direction in each specimen. In discussing this matter with Mr. (now Prof.) G. I. Taylor, he thought that it would be a straightforward, though possibly laborious, task to determine the relationship between the orientation of the axes and the distortion produced in a tensile test, and that by examining a number of specimens some general results might be obtained about the forces necessary to produce distortions of this type. He kindly agreed to join us in the work of testing these matters. Before the test contemplated could be carried out, however, it was necessary to obtain the help of an expert in crystal analysis by X-rays. Dr. A Müller accepted our invitation, and succeeded in devising a satisfactory method of determining the orientation of the crystal axes in single crystal bars by means of X-rays.

For the purpose in hand it was necessary to work with a square bar. As already mentioned, single crystals cannot be grown in square bar form. We had, therefore, to produce a round single crystal test-bar and then to machine it down until its section was square. The method of investigation adopted was as follows: Each face was marked by a scratch parallel to the length of axis of the specimen and by cross scratches at 0·5 in. intervals. The faces were numbered 1, 2, 3, and 4, so that when the specimen was placed upright in the testing machine the faces appeared in this order when the observer moved round the machine in an anti-clockwise direction. At each successive stage of the test the extension between each pair of cross marks was measured on each face. At the same time the angles between the cross scratches and the longitudinal scratch were measured in each case. In addition, the thickness of the specimens between pairs of opposite faces and the angle between neighbouring faces were also measured. These suffice to determine the nature of the distortion.

Measurements showed that near the ends of the specimen, where it was held in the grips of the testing machine, the measurements were not quite the same as those near the middle, but that the central portion was nearly uniformly strained There is a high degree of uniformity among the measurements of extension in the three middle compartments of each face, especially in the earlier stages of the test.

Measurements were made at extensions of 5, 10, 15, 20, 30, 40, 60, and 78 per cent., when the crystal broke. As the test proceeded the square section of the bar gradually disappeared, and the final result was a parallelepiped of remarkable form. The cross scratches, although remaining rectilinear, shifted by a definite angle which became markedly acute. When the specimen finally broke, it contained two very acute and two very obtuse angles.

Prof. Taylor and Miss Elam followed up this work with a paper published in 1925. In this they have described similar experiments made with several more specimens in order to find out whether the conclusions previously reached are general in their application and to settle several points which the previous experiments left in doubt. The chief result of their earlier work was to show that of the twelve crystallographically similar possible modes of shearing, the one for which the component of sheer-stress in the direction of shear was greatest was the one which actually occurred. The first object of the later work was to determine the orientation of the crystal axes of several specimens.

Assuming that the relationship outlined above holds in general, it is possible to predict the orientation of the plane on which slipping should occur. Three more single crystal test-pieces were stretched and their distortions analysed by the method already described. It was found that in each case the distortion was such as would be produced by shearing parallel to a single plane, and that this plane of slip was the one predicted. It was also found that the changes in orientation of the crystal axes relative to the axis of the specimen during the test were in good agreement with the prediction.

In the previous work it was not possible to make a detailed analysis of the deformation during the last stages of the stretching, but it was shown that the deformation ceased to be due to slipping on one crystal plane. Reasons were given for supposing that the deformation might be due to slipping on two crystal planes simultaneously, and it was shown that the crystal axis which formed the intersection of these two planes remained unstretched during the test, as it should if the distortion were in fact due to this cause. There are, however, a number of other types of distortion which might also leave this particular axis unstretched. In their later paper Taylor and Elam showed that for a small distortion the 'unstretched' cone passes through or very close to three other crystal axes, which, in fact, determine all the possible kinds of unstretched cone which can be produced by double slipping of the type contemplated. This completes the proof that the slipping in the last stages of the test is of this type.

When the crystal begins to slip on a second plane it seems likely that the rate of slip on each plane would be the same. In this way they would remain inclined at equal angles to the axis of the specimen, but it was impossible to verify this suggestion from the previous experiments. The second paper contains the test of this, and it is found that, although double slip does begin when two planes get to the position in which they make equal angles with the axes, the rate of slipping on the original slip plane is sometimes greater than it is on the new one. The two planes do not, therefore, necessarily remain at equal angles with the axis, but the process cannot be followed very far because the specimen usually breaks when only a comparatively small amount of double slipping has occurred.

A most interesting test described in this paper was that in which the authors distorted a single crystal test-piece, in which they predicted that from the original position of the crystal axes double slipping should begin at once. A specimen was found the axes of which corresponded very closely to this position, and it was found that double slipping did occur during nearly the whole extension. In this case it was found that the amount of slipping on the two planes was practically equal, and that the axis of the specimen remained very close to the (112) axis during the whole test.

A point of which Taylor and Elam made special mention was the extraordinary uniformity of the stretched specimens. They showed a photograph of specimen No. 68 which had been stretched to an extension of 70 per cent. To the eye it appears absolutely uniform. They gave numerical data as to the variations in extension of different parts of the specimen, and found that the average variation of ϵ was 0·0028 during the first 5 per cent. Up to 20 per cent. extension the variation did not exceed this figure; it then began to increase, until at the breaking point it rose to 4 parts in 100.

The chief conclusions drawn by the authors from the theory of fracture contained in their paper are—(1) that with a stress-strain curve of the type found by them, fracture of aluminium single crystals cannot occur by slipping on a single crystal plane, and (2) that the geometrical conditions alone imply that fracture takes place more easily when double slipping occurs than when all the slipping is confined to one plane.

Miss Elam and I have recently investigated the distortion of single crystal test-pieces of aluminium followed by subsequent heating. We have found that the crystals can be deformed so much as 7 per cent. without being destroyed on heating. Beyond this amount the metal recrystallises and breaks up into a number of smaller crystals the size of which depends on the amount of distortion. Near the fracture the crystals are smallest and they increase in size towards the shoulders of the test-piece. The recrystallised metal shows exceptionally straight crystal boundaries, and the crystals are frequently twinned.

We then made a detailed examination of the behaviour of two round single crystal test-pieces after successive increments of strain followed by heating. The orientation of the bar was first determined by means of X-rays, and the metal then extended 5 per cent. The position of the crystal axes was then determined, and it was found that the reflections on the photographic plate were not so well defined and were spread over a large reflecting angle. The crystal was then heated to 400°, 500°, and 600° C. and examined after various periods at these temperatures. No change appeared after this treatment. The nature of the X-ray reflections was unaltered, and there was no change in the position of the reflecting planes. After a second extension of 5 per cent. the positions of the reflecting planes were redetermined and the bar heated to 350° and 450° C. No change was observed. After heating at 550° C. the reflections that had been found previously had disappeared, but new ones were obtained in other positions.

A comparison of the reflecting planes from different parts of the bar, including opposite sides of the same reference plane, showed that it was still a single crystal, but that it possessed an entirely different orientation from that of the original. Moreover, the X-ray reflections now obtained were sharp and well defined as in the original crystal. Etching in caustic soda revealed a homogeneous structure. Further extension of 5 per cent. produced results similar to the first extension, and heating up to 600° C. produced no change. On heating after the fourth extension, however, the orientation was found to have changed once more, but the bar still remained a single crystal. The process was again repeated, and after the sixth extension a partial recrystallisation took place. Another single crystal test-piece was subjected to this treatment with exactly similar results. Here again the crystal moved successively into two new positions.

The Problem of the Origin of Species as it appeared to Darwin in 1859 and as it appears to us To-day.[1]

By Prof. HENRY FAIRFIELD OSBORN, For. Mem. R.S.

The first of these objects, that is, the establishment of a belief in descent with modification, was always held by my father to be the more important of the two; for I once heard him say, if a recollection of about fifty years' standing may be trusted, that "after all, evolution is the great thing, not natural selection."—LEONARD DARWIN, "Organic Evolution," pp. 1, 2.

NEARLY one hundred years ago Charles Darwin began to collect facts for "The Origin of Species," his immortal work, which was cautiously withheld from publication until 1859. There still prevailed the zoology of Linnæus and Buffon and the palæontology of Cuvier. In Lesson's "Mammalogie" (1827) the number of mammalian species is exactly 1124, as compared with the 13,450 species and subspecies of mammals known at the end of the year 1925. Birds increased from 3600 to 23,939; reptiles and amphibians from 543 to 9000; fishes from 3500 to 20,000. Darwin's species stood apart like isolated mountain peaks, whereas to-day living species and subspecies are often comparable to mountain chains composed of lesser peaks completely connected by ridges known as intergradations. It is not the number of species and subspecies which is significant, but the facts as to habit and habitat which are recorded with them. Similarly, it is not the number of fossil species now known as compared with those of Darwin's time, but the *linkage* of families, genera, species, subspecies, and even of 'ascending' and 'descending mutations' reaching back over hundreds of thousands, if not millions, of years.

This twenty- to one hundred-fold disparity in our knowledge simply intensifies our admiration for the courage of Darwin in boldly substituting a natural for a supernatural conception of the origin of species. It is true that Darwin's most influential authority was not the current zoology and palæontology of his day but Nature itself, whereby even in 1859 he absolutely established the Law of Evolution, as well as the directing and standardising principle of Natural Selection. It is, however, not this broader aspect of evolution, but the more concrete problem of the *modes* and *causes* of the origin of species which we are considering to-day.

Let us re-examine these causes in the light thrown by naturalists and observers on the invertebrates and vertebrates as distributed over the great continents of Europe and Asia, of North and South America, of Australia, considered not alone with their present boundaries but also with their former land connexions secured by elevation to the hundred fathom line. In this connexion I present a new zoogeographic and palæogeographic map of the world, prepared with the aid of Bartholomew of Edinburgh. We shall see that the results of zoological and palæontological research are entirely harmonious and concordant, but that zoology, while clearly teaching certain principles of the origin of species, leaves blank many gaps which are completely filled by palæontology.

Thus these two branches of biology are complementary in demonstrating that, through observations after the very naturalistic manner of Darwin in the voyage of the *Beagle* and through the very Lyell-Darwin methods by which the natural origin of species was originally discovered, *the problem of the origin of species has entirely changed in the last hundred years.* In fact, were the great naturalist living to-day, he would be foremost in modifying his own opinions, speculations and theories.

Greatly enhancing the value of the recent work of our field naturalists is the fact that the results reached in fishes, amphibians, reptiles, birds and mammals were recorded entirely independently of each other. Where the conclusions reached are harmonious or concordant they have the convincing value of entirely independent testimony. Also, these results are doubly valuable because they are for the most part assembled without biological purpose or intent, not to prove or to disprove any particular theory, but recorded simply as actual observations.

This is generally true of all field naturalists, who are more concerned about Nature than about the interpretation of Nature. The interpretations upon which our field naturalists do venture, such as the 'direct action of environment,' and 'Lamarckian inheritance,' are often lacking in real biological analysis. For such analysis, therefore, we must allude to five biological principles which have developed from laboratory experiments, and the generalisations growing out of them, beginning chiefly in the year 1880. These are as follows:

(1) Weismann's sharp distinction of the germ-plasm from the body plasm, from which follows the equally sharp distinction between truly germinal specific characters and bodily modifications by environment or habit; (2) the experimental failure of the inheritance effects of adaptive habit, known as Lamarckism; (3) the apparent failure of the environment to modify immediately the germ-plasm in creating adaptive specific characters; (4) the sharp limitations of the originative powers of Natural Selection as conceived by Darwin; (5) the sharp distinction between the continuous and discontinuous (or mutational) origin of specific characters.

In fact, the outstanding speculations of Darwin's and Herbert Spencer's time as to the causation of the origin of species have been pared down by laboratory analysis to a mere vestige of their former selves, and the overweening confidence of one school of causation after another has been displaced by diffidence, doubt, or even agnosticism, as expressed in the final address of William Bateson, whose recent death we lament at this meeting. To sum up, intensive laboratory and experimental research has added vastly to our knowledge of the functions of animals and of the heredity mechanism but has greatly increased the difficulties

[1] Read before Section D (Zoology) of the British Association, at the Oxford meeting, August 5, 1926. This is the fourth of a series of papers on the origin of species, the first having appeared in NATURE, June 13 and 20, 1925, under the title, "The Origin of Species as Revealed by Palæontology."

inherent in the problem of the origin of species. It is the *modes* and the *causes* of the onward progressive movement of the germ-plasm resulting in the consecutive origin of new adaptive specific forms which are rendered still more mysterious by the negative results of laboratory research.

DISTINCTION BETWEEN SPECIATION AND MUTATION.

So far as the *modes* of the origin of species are concerned, these negative results of the laboratory are more than offset by the positive results obtained by our field naturalists and explorers who are independently discovering a considerable number of species-in-the-making at the present time. In other words, we now understand the contemporary origin of species after modes and under conditions wholly unknown to Darwin in 1859. Geographic *isolation*, to which Darwin's attention was first directed by Wagner, with all the incidental influences of physical or chemical change, of enforced change of habit, of competition with a new life environment, perhaps of stimulus to the germinal energies themselves, seems to constitute the chief complex of causes in the origin of new species; this complex is summed up in the principles which Osborn terms *tetraplasy* and *tetrakinesis*. An extreme phase of isolation is *insulation*, where species are scattered among a number of islands. A like isolating mode among fishes is seen in the complete separation of rivers and streams formerly connected. In this complex of four coefficient causes, all involving energy, the specific germinal substance itself undergoes change, extremely slow but continuous, so that a new stage is very gradually reached, formerly known as a 'geographic variation' but now known as a 'subspecies.' Between subspecies living in islands and separated rivers there are naturally no *intergrades* or intermediate stages, but in a number of independent examples among fishes, amphibians, reptiles, birds and mammals, true intergradation has been observed linking one subspecific form with another in a continuous germinal life-chain. Such survival of intergrades may be instanced as proof of *complete continuity* between subspecies and, consequently, between species.

This appears to be the normal and natural mode of origin of the greater number of specific forms as observed in zoology; such mode has been termed 'speciation' by recent British and American authors. In exactly the same field of observation and by the same observers, apparently as an abnormal mode due to some irregular influence on the specific germ-plasm, is seen the discontinuous or sudden origin of new characters, ranked by some observers as specific, after the manner termed 'chance variation' by Darwin and 'mutation' by De Vries. *Mutation* thus appears to be a real phenomenon, but a relatively rare one; such mutational origins need to be protected by geographic or climatic isolation from interbreeding with normal species.

Thus *speciation* through continuity stands in contrast with *mutation* through discontinuity. There is no question as to germinal change in mutations, but may the same be said of subspecies? In answer to this doubt it has recently been shown by experiment (Sumner 1924) that many, if not all subspecific characters are ***stable under changed conditions of environment***. Consequently, while under suspicion as to reality, often vexatious and unconvincing, and always annoying to the systematist, ***well-authenticated subspecies are of priceless value to the biologist who seeks to ascertain the conditions under which new species arise.*** It proves that many 'geographic variations' and 'subspecies' are really germinal transitions, intermediates and intergradations from 'species' to 'species' of the higher kind known to Darwin.

The above is a summary of principles gathered from a very large number of independent observers whose names will be fully recorded with the titles of their papers in the complete series of notes on which the present paper is based. Outstanding names are those of Adams in the gastropods, Jordan, Berg and Regan in the fishes, G. A. Boulenger in the amphibians, E. G. Boulenger in the reptiles, Chapman and Griscom in the birds, Osgood and Sumner in the mammals. The whole list of observers in the vertebrates alone comprises more than a hundred names. For the annotation of this extensive literature I am indebted to members of the corps of zoologists of the American and British Museums and of the Zoological Society of London.[2]

EXAMPLES OF GEOGRAPHIC ISOLATION AND SPECIATION.

It appears that speciation arises only where one or all of the energy coefficients of Osborn is changed. In amphibia especially, geographic isolation does not invariably result in the origin of new species, because all the conditions of the new habitat may be identical with those of the old. A most striking example of complete intergradation between 'species' is that of the molluscan genus Io of the Tennessee River, which now presents all the living intergrades between the smooth and the spinose forms as we pass downstream. In fishes, skeletal intergrades are observed as we pass from northern to southern waters (Berg) or from a colder to warmer marine habitats; these intergrades consist in the number of vertebræ, of fin rays and of scales, and in body form and colour, and Berg concludes that all the individuals of certain geographic areas simultaneously produce similar new specific characters.

Among amphibians the entire region around the Mediterranean affords G. A. Boulenger a series of subspecies of the edible frog, *Rana esculenta*, more or less connected by intergrading forms. Among reptiles E. G. Boulenger observes the speciation of the skink, *Chalcides ocellatus*, a species which, like the edible frog, surrounds the Mediterranean, in which the difference between two isolated subspecific forms is so great that *were it not for the wonderfully complete manner in which they are connected they could not be denied full specific rank*. As among fishes, intergradations are observed in all the skeletal characters, as well as in the colouring and the scales. Completely supporting these observations are those of many of the recent herpetologists who conservatively use the word 'variety' where other authors use the word 'subspecies,' who imply that intergradations occur wherever a sufficiently large number of specimens are examined. Chapman, with extensive collections of South American birds at his command, records exactly similar results:

[2] These data will be published in full in a sequel to the present paper, in the *American Naturalist*, No. 5, in the series on the origin of specie

The ornithologist finds large forms occupying colder areas, dark ones humid areas, and pale ones arid areas; and as the [environmental] conditions which obviously produce these variations in size and colour merge one with the other, so do the [specific and subspecific] forms themselves intergrade. That these variations are inherent [*i.e.* germinal, constitutional, hereditary] and not merely the temporary impress of physical environment on the individual, is apparently shown by the fact that they are often as well marked in the nestling as in the adult.

Chapman also observes a distinct case of 'mutation' within the genus Buarremon in the presence of a black pectoral feather-band, which is established as a specific character by isolation or geographic discontinuity. Like the single case with black dorsal band observed within the genus Troglodytes, the mutation does not intergrade and is thus recognised as of discontinuous or mutational origin. Stresemann finds partial melanism as well as albinism arising as not infrequent mutational characters, but fails to show that these are adaptive. Chapman and Griscom in their North and South American field work distinguish clearly between intergrading and non-intergrading kinds of birds. In a collection of 1500 specimens of the house wren, Troglodytes, these observers have noted a considerable number of cases of *complete* intergradation between subspecies, and those familiar with the marked physiography of South America, with (*a*) its cold and arid Pacific coastal belt, (*b*) its Andean Mountain chain subdivided by Chapman into numerous vertical life-zones each clearly demarcated until we reach the boreal summits, (*c*) its vast Amazonian forest plain, (*d*) its pampas and plains of the south-east, and (*e*) humid forests bordering the Straits, may anticipate wide speciation in other forms of animal life in this continent. It is noteworthy that these observers have discovered in Troglodytes only one example of mutation in the sense of De Vries. It cannot be questioned that isolation is the most important factor in the speciation of birds, especially in its extreme form of insulation. As an example of wide isolation without speciation, the house wren of Florida, *T. ædon ædon*, exhibits the same characters as those of Tierra del Fuego, but in the intermediate regions another species, *T. musculus*, exhibits a large amount of subspeciation and several complete intergradations.

Among mammals the great transverse geographic range from Scotland across Eurasia and North America to New Brunswick, Canada, of three species of the deer family, affords a striking example of geographic speciation; the stag (Cervus) yields twenty-three species and subspecies; the moose (Alces) yields eight subspecies; the reindeer (Rangifer) yields twenty-one subspecies. This is in wide contrast to the knowledge of Darwin (1837–1859), to whom were known only two species of stag, one species of moose, and one species of reindeer. Far more significant, however, are the observations of Osgood and Sumner on the deer-mice of the genus Peromyscus, which range through the temperate region of North America to the Pacific coast. From a collection of 30,000 specimens Osgood finds that a subspecies is characteristic of every distinct climatic region and sub-region. These subspecies listed by Merriam and Osgood have been accepted with great reluctance, especially by naturalists unfamiliar with the excessively sharp geographic and climatic barriers of the western United States. Our hesitation to accept these subspecies as of real germinal or genetic value has been entirely removed by the persistent observations and experiments of the biologist Sumner, largely in the identical collecting grounds of Osgood, and we must welcome these combined observations and experiments as the most convincing demonstration of the principle of *speciation continuity* thus far afforded. Between at least six of these subspecies complete intergradations occur. Classification becomes like dividing the lines of the spectrum. After eight years of transfer from an arid to a humid environment, or vice versa, these subspecies retain their original characters. Even profound change of environment does not yield a new subspecific form, nor are changes of habit inherited in eight years of experiment.

(1) The summary of eight years' experiment proves the comparative stability of subspecies of the Deer-mice (Peromyscus) under very marked new environmental physical conditions. (2) Merriam-Osgood subspecies are proved to be stable under changed conditions of environment, by transplantation experiments; *i.e.* a desert subspecies, *P. m. sonoriensis*, reared for eight years in a humid environment, is entirely unmodified in the direction of the humid subspecies *P. m. gambeli*. (3) This doubly proves (*a*) that characters of the desert *P. m. sonoriensis* are germinal, not environmental; (*b*) that humid environment makes no modification whatever toward increased depth of colour in eight years and in seven to twelve generations. (4) Similar results from transplantation of *P. m. rubidus* and *P. m. sonoriensis* are obtained: reared in an entirely new environment, they do not converge toward each other but toward local humid species *P. m. gambeli*.

SPECIATION A SECULAR PHENOMENON.

Whereas an inheritable mutation may be produced by a single experiment, 40,000 years, the lapse of time since the last glaciation, is a moderate estimate of the time required to produce a subspecies. In the case of all the genera cited above—Cervus, Alces, Rangifer, Rana, Chalcides, Troglodytes, Peromyscus—we are observing subspecies arising in a region which was profoundly affected by the fourth glaciation with its pluvial climate, a region in which new subspecies have arisen *pari passu* with the modern demarcations of habitat and of habit. That speciation is an incredibly slow process is attested by the case of the newly discovered Pliohippus of Leidy, which early in Pliocene time assumed all the characters of the modern Equus. The entire speciation process of plants and animals has been going on perhaps for a thousand million years, as estimated on purely physical grounds, and in a recent conversation with Sir Ernest Rutherford it was agreed that another thousand years of research may be required for an understanding of the highly complex physico-chemical basis of life.

CONCORDANT OBSERVATIONS IN ZOOLOGY AND PALÆONTOLOGY.

As distinguished from the speciation observed in zoology, in palæontology we deal with secular speciation, in which, quoting from the first of Osborn's series of

papers on the origin of species, we observe the adaptive action and reaction of the heredity germ over long periods of time. We also observe the secular action of natural selection (Darwin's selection factor), the secular direct reaction to environment (Buffon's factor), the secular adaptive action of habit (Lamarck's factor), the secular adaptive reaction to the living environment (Darwin's factor). We sharply separate Darwin's factor of selection, which has no energy content, from the above four energetic forces of evolution, namely, heredity, physical environment, living environment, and individual development or ontogeny. This is the principle of tetraplasy and tetrakinesis.

This momentary lapse into speculative as distinguished from purely observational consideration of the problem of the origin of species may clarify the transition from zoology to palæontology.

In palæontology an entirely new series of principles is discovered in speciation which are quite beyond the eye of the zoologist. Chief among these new principles is that dimly perceived by Darwin in the words 'analogous variation'; it is that of germinal or evolutionary trend in a definite direction, the 'mutations richtung' of Neumayr. Out of this springs Osborn's principle of *rectigradation* observed in the rise of adaptive characters from the germ-plasm, that is, new specific characters which pass continuously from the most rudimentary and inefficient into the most efficient and highly developed stages. It may be a matter of interest to members of the British Association to recall that this principle was presented to the Association in 1889 by the present speaker. Through unbroken observation during the intervening thirty-seven years this rectigradation principle has been confirmed in four great orders of hoofed mammals, namely, the horses, the rhinoceroses, the titanotheres, and the proboscideans. Research on the two latter groups fills two great monographs aggregating nearly a million words and covering, in the case of the Proboscidea, the analysis of the mode of origin of more than 350 species and, in the case of the titanotheres, the chief stages of specific development extending from Lower Eocene through Lower Oligocene time, when these animals suddenly disappear.

An epitome of these observations is presented in three diagrams in which the three outstanding principles discovered in palæontology are observed: First, the unbroken continuity of speciation, which becomes absolute as the gaps are filled by discovery. Second, the constitutional predisposition to speciate in certain predetermined directions which must be inherent in the germ-plasm of ancestral forms. Third, that these constitutional predispositions are not released except through adaptive reaction to new conditions of life; they are not, therefore, of the nature of inherent perfecting tendency, but, rather, of the nature of a *potentiality* to appear when the need for them arises. For example, the rhinoceroses have the potentiality of developing two horns, an anterior horn on the nasal bone and a posterior horn on the frontal bone. But in the fourteen branches into which this great subfamily subdivides in its migrations to all parts of the earth, this double potentiality is seldom availed of, sometimes not availed of at all.

CONCLUSIONS.

We seem to have reached an entirely new era in research on the problem of the origin of species, marked by the decline and death of speculations and theories advanced upon the very limited knowledge of the first half of the nineteenth century. Through zoology and palæontology we have reached a solution of the least difficult half of the problem with which Charles Darwin was confronted: we know the *modes* by which subspecies and species originate; in fact, there is little more on this point to be known. But this very knowledge renders the problem of *causes* infinitely more difficult than it appeared to Darwin. The causes of 'variation,' to use the term he employed for the evolutionary process, lie in the way before us. They may be resolved or they may prove to be beyond human solution. We must resolutely face these alternatives, and in the meantime continue our synthesis over every field of biologic research.

The Geographical Distribution of Magnetic Observatories.

By Dr. C. CHREE, F.R.S.

THE provision for observational work in terrestrial magnetism is different in kind in different countries, and in some countries—Great Britain, for example—the provision made is of more than one kind. The object in view may be purely utilitarian, or purely scientific, or partly both. Originally the provision of information necessary for the use of the compass was the one utilitarian object generally recognised. To secure this object to the best advantage, the natural course is to make a single department responsible for the running of magnetic observatories, the taking of field observations and the preparation of charts. Thus, in the United States the Coast and Geodetic Survey controls the whole of official terrestrial magnetism. The number and position of the observatories—Sitka, Cheltenham, Tucson, Vieques (Porto Rico), and Honolulu—is determined primarily by survey considerations. The same idea prevailed to a certain extent in India, but the oldest magnetic observatory, Alibag—regarded as the continuation of Colaba, Bombay—represents a more usual form of development.

In most countries terrestrial magnetism has not been an independent plant, but from the point of view of astronomers and meteorologists has been a parasitical growth on astronomy or meteorology. Greenwich may perhaps be regarded as an example of this. At present most magnetic observatories are under the meteorological service of the country, and one of the two international associations concerned with the subject is the Magnetic Commission of the International Meteorological Committee. It is under its auspices that a selection of international quiet and disturbed days is made at De Bilt, Netherlands. The other international association, the Section of Terrestrial Magnetism and Electricity of the International

Union of Geodesy and Geophysics, represents the more distinctly scientific aspects of the subject. Its existence distinct from the Section of Meteorology is largely due to the independent position assigned to terrestrial magnetism in the United States and some other countries.

In France—as is still the case in Germany, Denmark, Holland, Belgium, and Portugal—terrestrial magnetism used to be in the main a branch of meteorology, but it now comes under the Institute of Geophysics, presided over by Prof. Maurain, of Paris. In Italy there was once an observatory at Rome under the Meteorological Office. But Rome—like Kew of later years—suffered from artificial disturbance and had to be given up, and Italy remained for many years without a continuously recording magnetic observatory. It succeeded after the War to the observatory maintained at Pola by the Austrian Admiralty, which is now controlled by the Italian Hydrographic Office.

Of the observatories independent of State control, the most important are those of the Jesuit Order and of the Carnegie Institution of Washington. The former group includes Stonyhurst—one of the oldest magnetic observatories now existing—Ebro (Tortosa) and Lukiapang (successor to Zi-ka-wei) in China. The Carnegie observatories at Watheroo (Western Australia) and Huancayo (Peru) are of recent creation.

In Bulletin, No. 5, 1924, of the International Section of Terrestrial Magnetism and Electricity, 66 magnetic observatories are included in the list on pp. 146-148, but some of these had not been active for some years, and a few, for example Kew, are now extinct. The number may seem large, but it means only one observatory per three million square miles of the earth's surface, while the diversity in the phenomena to be recorded is very great. Further, the distribution is very irregular. Of the 66 observatories mentioned above some 30 were in Europe, and only 13 were in the southern hemisphere. Only three were north of 60° N., and only two were south of 40° S. The regions of the globe in which observatories are particularly scarce call for our special consideration.

Until a few years ago Pavlovsk (59° 41′ N.) was the most northerly regular station provided with magnetographs. No publications from it or other Russian observatories for years after the commencement of the War were available until comparatively recently. But it would seem that unbroken records were obtained at Pavlovsk and Kasan in Russia, and at Ekaterinburg in Siberia. Records were also obtained at Irkutsk, or at Zuya in its neighbourhood, down to 1920. The Russians have also established a new station at Matochkin Shar (73° 15′ N.), in Nova Zembla, a neighbourhood where Prof. Birkeland had a temporary station in 1902–3. This is the most northerly station on the international list. From information recently supplied we learn that it is equipped with Eschenhagen magnetographs recording D, H, and V (declination, horizontal force and vertical force), the sensitiveness of these instruments being respectively 1′·0, 22·6γ and 5·7γ per mm. More suitable values for a station where H is very low and disturbance large, would be 2′ or 3′ per mm. for D, and 10γ for H and V. The magnetograph room itself seems to be of wood, but the instruments stand on a concrete and brick foundation. This foundation should be satisfactory if it is non-magnetic, a property, however, which is rather unusual in brick. Further, Russian observatories seem also in contemplation at Taschkent and in Eastern Siberia, a part of the world unrepresented at present.

Of the two other observatories on the international list north of 60° N., one, Sodankylä (67° 22′ N.), is run by the Finnish Government, which of late years has also been active in survey work. The third of the new high latitude stations, Lerwick (60° 9′ N.), in the Shetland Islands, was instituted by the Meteorological Office, and magnetographs were in operation in 1923. Another high latitude station of comparatively recent origin calling for notice is Meanook (54° 37′ N.) in Canada. This was only partially equipped in 1924, and one of the resolutions passed by the Section of Terrestrial Magnetism and Electricity at its meeting in that year at Madrid emphasised the importance of full equipment. Meanook is one of the nearest stations to the north magnetic pole. Yet another high latitude observatory is being instituted by the Danish Government at Godhavn (69° 15′ N., 53° 14′ W.) in western Greenland. Pavilions for absolute observations and for magnetographs connected by a corridor form a single building. An important feature is that the equipment includes two complete sets of magnetographs, one of low sensitiveness, so as to make provision for large disturbances.

Observatories in high magnetic latitudes (that is, latitudes where dip is high) have special difficulties to contend with. Magnetic disturbance is large, and H being small, changes in D are enormous, rendering ordinary D magnetographs unsuitable. On the other hand, small changes of dip represent such large changes of V that ordinary dip instruments are unequal to the satisfactory determination of base line values for V curves. It is thus a matter of general interest that the National Physical Laboratory has under construction an instrument for measuring V directly. The desirability of such an instrument was also the subject of a resolution at Madrid. High latitude stations are of special importance, not merely because they record magnetic disturbances in the regions where these are most developed, but also on account of the light they may throw on the relation between magnetic and auroral phenomena. The importance of this relation has been increased by the development of radio, and the evidence that has recently been obtained as to the influence on radio of a 'conducting layer' at about the height which Prof. Störmer has found for the lower level of aurora. So far at least as latitude is concerned, Lerwick should be favourably situated for combined observations on terrestrial magnetism and aurora. But the full utilisation of the opportunities presented by such a station calls not merely for special knowledge and equipment, but also for an ample and vigorous staff, as a lot of night work is involved under probably severe climatic conditions.

Another region where magnetic observatories have hitherto been sparse includes the geographical equator. The international list contains no station between Buitenzorg (Batavia, 6° 11′ S.) and Kodaikanal (10° 14′ N.), and a footnote supplies the regrettable information that Kodaikanal stopped recording in

1923. This will leave more than 20° of latitude unrepresented between Batavia and Antipolo (14° 36′ N.). Kodaikanal was one of the stations supported by the Indian Survey, which has also closed down observatories at Barrackpore (22° 46′ N.) and Toungoo (18° 56′ N.), thus leaving only two magnetic observatories, Alibag and Dehra Dun, in the whole Indian empire. The fact that, as compared with pre-War times, magnetic observatories have fared worse in India than in Russia seems to afford food for reflection. If Kodaikanal is an unsuitable site, as is rather suggested by remarks in some of the Indian Survey publications, the resuscitation of Trivandrum, memorable for the work of J. A. Broun, would provide a station nearer to the equator than any existing observatory in the northern hemisphere.

Other areas within the British Empire where magnetism is somewhat poorly represented are South Africa and Australia. There was once a magnetic observatory at Cape Town, and a new observatory somewhere else in South Africa has been talked about, but at present the Royal Alfred Observatory in Mauritius seems to be the only one in that part of the world. Melbourne was once the site of a magnetic observatory, but has long been unsuitable for that purpose. Recently an observatory has been set agoing at Toolangi in Victoria, but that seems the only observatory in Australia, with the exception of Watheroo, which belongs to the Carnegie Institution of Washington.

New Zealand has a magnetic observatory at Christchurch, and with assistance from the Admiralty and the Carnegie Institution is also maintaining what was originally a German observatory at Apia, Samoa. It is scarcely necessary to say, in view of the scarcity of magnetic observatories in or near the Pacific Ocean, that the stoppage of Apia observatory would have been a great misfortune.

The latest observatory of the Carnegie Institution, Huancayo (12° 3′ S.), is in a way unique from its proximity to the magnetic equator. Dip there at present is less than 1°, and its measurement must present unusual features. Huancayo is situated, moreover, in a continent, South America, where additional magnetic observatories are badly wanted.

Obituary.

SIR WILLIAM RIDGEWAY.

WILLIAM RIDGEWAY, a son of the Rev. J. H. Ridgeway, of Ballydermot, King's County, was born in 1853; he had a brilliant career in Trinity College, Dublin, and later at Gonville and Caius College, Cambridge, graduating as fifth Classic in 1880, and was elected a fellow of his College. In 1883 he was appointed to the chair of Greek in Queen's College, Cork, and while holding that appointment he resided for five months each year in Cambridge. In 1892 he was elected to the Disney professorship of archæology in Cambridge, and shortly afterwards resigned his chair at Cork. He was re-elected a fellow of his College, and had also been Brereton reader in classics since 1907. He was Gifford lecturer in natural religion, University of Aberdeen, in 1909–11; Stokes lecturer in Irish archæology, Dublin, 1909; and Hermione lecturer in art, Dublin, 1911. He was president of the Royal Anthropological Institute, 1908–10; of the Anthropological Section of the British Association, 1908; and had been president of the Cambridge Philological, Antiquarian, Classical and Anthropological Societies. He was elected a fellow of the British Academy in 1904, and was a foreign member of various learned societies in Europe. His learning was recognised by other universities, and he had conferred on him Hon. D.Litt. Dublin, 1902; Hon. D.Litt. Manchester, 1906; Hon. LL.D. Aberdeen, 1908; and gained the Sc.D. of Cambridge for his work on the horse. He was knighted in 1919. He wrote numerous contributions to classical, philological, anthropological, zoological and other journals, and the following books: "Origin of Metallic Currency and Weight Standards," 1892; "The Early Age of Greece," 1901; "The Origin and Influence of the Thoroughbred Horse," 1905; "The Origin of Tragedy," 1910.

This bare enumeration of the academic distinctions and of the writings of Sir William Ridgeway will serve to show the wide extent of his erudition and the great range of his interests. These were constantly exhibited when he joined in discussions at classical and scientific societies, in which he usually gave a free rein to his sense of humour, and also to caustic criticism. His strong personality and the definite views he expressed vividly in speech and writing, combined with his love of controversy, sometimes strained the forbearance of many friends, even occasionally to the breaking point. He was a man of pronounced likes and dislikes, and it was often a moot point whether he was not as dangerous to the causes he espoused and to his friends as to his enemies, for he was liable through friendly enthusiasm to overstate the case at issue. He entered wholeheartedly into a fray, whether it was Irish education, the Irish and English Anglican Church, or University politics, as those can testify who remember the discussions on the degrees for women and on compulsory Greek in the University of Cambridge.

Sir William was emphatically a driving force in the University, and spared no pains in furthering the well-being of the institutions to which he belonged, to take but two examples: the Cambridge Antiquarian Society and the Museum of Archæology and Ethnology. It was due to his energy that a lectureship in ethnology was instituted, and again largely to him that nine years later it was converted into a readership; in this and other ways he was instrumental in founding the Cambridge School of Anthropology. He very early recognised the value of ethnology in elucidating obscure points in classics and archæology; in some respects he was a pioneer in these comparative studies, and he delighted to recall how his heterodox views later gained acceptance from more conservative scholars.

Sir William stimulated very many students, naturally mainly in classical archæology, of whom a considerable proportion have gained great eminence, and he was careful to keep in frequent correspondence with them; but he also had a large number of correspondents throughout the world on an amazing variety of

subjects, from Asiatic ritual dances to currency and zebras.

Those who were privileged to see Sir William's family life gained another view of this very remarkable man. His love for his wife was as apparent as it was deserved, for Lady Ridgeway devoted her life to her brilliant husband, and no one will ever know what he owed to her. She was his prop for very many years as his eyesight increasingly failed, and she dispensed gracious hospitality to his friends in their charming home at Fen Ditton. Her sudden death at the end of May was a terrible blow, and though he gallantly tried to overcome his desolation and to take up the threads of his old life, he was a broken man until death mercifully took him in his sleep during the night of August 11: a peaceful ending for a strenuous and militant life.

A. C. HADDON.

WE regret to announce the following deaths:

Mr. William Fawcett, lately Director of Public Gardens and Plantations, Jamaica, on August 14, aged seventy-five years

Prof. Robert Gnehm, professor of technical chemistry, and afterwards director of the Technical High School, Zurich, who was known for his investigations on dyeing processes and dyestuffs, aged seventy-four years.

Dr. J. F. Hall-Edwards, president of the British Electro-Therapeutic Society, and a pioneer in the field of medical radiology, on August 15, aged sixty-seven years.

News and Views.

THE meeting of the British Association at Oxford which ended on August 11 has been memorable in many ways; and not least for the specially interesting character of the proceedings at the concluding gathering held at the Examination Schools. The message received from the Prince of Wales as president summed up in felicitous language the aims and prospects of the cause of science, the advancement of which it is the object of the Association to promote. The message also conveyed, in graceful terms, the president's appreciation of, and thanks for, the efforts made by all concerned to render the Oxford meeting of 1926 one of the most successful in the records of the Association. The reply read by Sir Oliver Lodge as chairman gave due expression to the gratitude felt by the members assembled at Oxford for the keen personal interest and sympathy shown by the Prince in the work of the Association, notably in his inaugural address.

THE speech delivered by Sir Oliver Lodge bore eloquent testimony to the world-wide charm exercised by Oxford over all who can be touched by the long history of western civilisation and culture. The well-known eulogy by Matthew Arnold, marked by graceful fancy and poetic feeling, and not without a light suggestion of penetrating humour, came with especial force and acceptance from one so capable of giving it its full effect as Sir Oliver Lodge. The significance of the presence of guests from overseas and from foreign countries had been emphasised by the Prince in his message, and was driven further home by the chairman of the meeting. The speeches of Prof. M'Murrich and Prof. Osborn, the latter of which concluded the meeting, showed that they too, as visitors and guests from overseas and abroad, fully appreciated the claim of science for international co-operation and fellowship The final meeting at the schools was especially well attended, and formed an excellent conclusion to a very successful gathering.

AMONG several interesting papers presented to the Chemistry Section of the British Association at Oxford was a contribution by Mr. J. J. Manley on "The Union of Mercury and Helium." Judging by a lengthy report of Mr. Manley's paper in the *Times* for August 11, the author does not appear to have carried his investigations beyond the stage described in his letter to NATURE of April 24 last, except that he now believes that only one helide --HgHe—is formed, whereas in the letter he stated that he had obtained experimental evidence of the existence of two—$HgHe_{10}$ and HgHe. The evidence for union appears to be based upon the disappearance of free helium when it is submitted to the action of the electric glow discharge in contact with purified mercury, and upon a slight increase in refractive index as the action proceeds. The presumed compound is apparently decomposed by heat, so that its composition could be deduced from the difference in weight of 'uncombined' mercury before and after the experiment. As this difference is exceedingly small—of the order of 236 millionths of a gram—it is clear that Mr Manley is encountering very great experimental difficulties, and bearing in mind the somewhat similar work of Miethe and Stammreich on the alleged transmutation of mercury into gold (NATURE, May 29, 1926), it is obvious that further investigation is required to dissipate or confirm the doubts that are held concerning the author's conclusions. Should those doubts be dissipated, Mr. Manley's work will constitute a discovery of very great importance.

IN the issue of the *Times* referred to, a leader-writer refers to Mr. Manley's contribution as a "startling announcement," as if it were novel, but actually the claim was first announced by Mr. Manley in these columns more than twenty months ago (NATURE, December 13, 1924). It is perhaps asking too much to expect a leader-writer, even in the *Times*, to be conversant with all that appears in our correspondence columns, but the incident directs attention once more to the need of adequate scientific representation on the staffs of our leading newspapers, and it also testifies to the value of the work done by the British Association in affording opportunity for lay writers to proclaim from the house-tops matters

of scientific importance that otherwise may be lost in the pages of scientific periodicals. The opinion is frequently heard that announcements of great discoveries at meetings of the British Association are less frequent than of yore, and although there is little more valid evidence for this opinion than for that concerning the diminished severity of our winters compared with those of, say, fifty years ago, the belief is probably to some extent responsible for the unbridled romance with which the popular writer is apt to invest his accounts of scientific achievements. The first duty of the newspaper man is to make a 'story,' and to this end he gives free rein to his unscientific imagination by supplying or suggesting sensation where it is not called for, or by elaborating relatively unimportant details at the expense of the main issue; he is also peculiarly susceptible to the temptation of treating the new as of necessity true, and occasionally, as in the present instance, of treating the true as necessarily new.

A STRONG earthquake was felt in the midland and western counties of England and in Wales at 3.58 A.M. (G.M.T.) on Sunday, August 15. From the accounts so far received it appears that the shock was felt over a nearly circular area 225 miles in diameter, and containing, therefore, about 40,000 square miles. The centre of this area lies a few miles to the south-east of Hereford, and it is worthy of notice that the shock was strongest in this city and Ludlow and in some of the villages between. A few chimneys fell at some of these places, but damage slight would not entitle the earthquake to a higher degree of intensity than 7 of the Rossi-Forel scale. During the last forty years British earthquakes of the same intensity have disturbed areas ranging from 25,000 to 63,000 square miles. The position of the roughly determined centre suggests that the recent earthquake may be connected with the twin-centres in a northwest-southeast line near Hereford and Ross, which gave rise to the strong earthquakes of 1863, 1868, and 1896. These disturbed areas of about 85,000, 41,000, and 98,000 square miles respectively. As regards intensity and disturbed area, the recent earthquake closely resembles that of 1868, and it is not impossible that, as in that year, the Ross focus was mainly responsible for the disturbance. The much slighter shock of January 26, 1924, was not directly connected with the others, for the axis of its disturbed area runs in a northeast-southwest direction through or near the Hereford focus.

AFTER a busy professional life of forty-three years, Prof. T. Turner is retiring on September 30 from the Feeney chair of metallurgy in the University of Birmingham. Taking the Associateship of the Royal School of Mines with the De la Beche medal in 1883, Prof. Turner was appointed demonstrator in chemistry at Mason College. A few years later he became lecturer in metallurgy, and when the chair of metallurgy was instituted in the University, he was appointed professor and has held the position for nearly a quarter of a century. Prof. Turner's own research work has dealt with silicon in cast iron, the production of wrought iron and steel, the hardness of metals; volatility, density and other properties of metals and alloys. He is a past president of the Institute of Metals, having also served as treasurer. He is a member of council and Bessemer Gold Medallist of the Iron and Steel Institute. He is an honorary member of various metallurgical societies in the Dominions, the United States, and on the continent. In his own University, a gold medal has been instituted to commemorate his services to metallurgy. His best known book is the "Metallurgy of Iron," which has passed through several editions.

THE School of Research in Metallurgy at the University of Birmingham, under the able guidance of Prof. Turner, has done much original work, and has contributed in no small degree to the amazing progress in metallurgical science which has taken place during the present century. The past and present students and friends of the metallurgical department of the University and of its retiring professor, have decided to make a presentation to him in the immediate future. The subscription list is open to all who feel inclined to associate themselves with the movement; members of the local section of the Institute of Metals and of the Birmingham Metallurgical Society are supporting the scheme. Several local firms have also intimated their desire to subscribe. Further information and subscription forms may be obtained on application to Dr. T. B. Crow, hon. sec. to the testimonial committee, at the University, Edgbaston, Birmingham. Prof. Turner is proposing to reside at Leatherhead, Surrey, in order to keep in close touch with his interests in London, and in extending to him and Mrs. Turner our best wishes for further years of health and happiness, we will be voicing the sentiments of his very large circle of friends.

ALL true lovers of plant life will be interested to hear of the exceptionally well thought-out scheme propounded by Dr. L. Cockayne, the doyen of New Zealand botanists, for the setting apart of the Wilton's Bush Reserve, about three miles from the capital city of Wellington, N.Z., as an "open-air museum for plants native to New Zealand." The New Zealand flora is unique, not only in the beauty of its forests, its ferns and its alpine associations, but also in certain aspects of the lines of evolution which it has undergone, such as, for example, the replacement of a xerophytic type of foliage in the young plants of a number of species by a mesophytic type when well grown, this being exactly the opposite to what happens in the well-known case of the Australian phyllodineous wattles. Dr Cockayne propounds a scheme with four main points in it, as follows:—(1) A well-grown collection of all possible species from the flora of New Zealand, the Kermadecs, Stewart Island, Chatham Islands and the subantarctic islands, so far as the limitations of the soil and climate of the proposed site will allow. (2) Representations of the leading plant-associations found in the Dominion, just as they existed in primeval New Zealand. Many of these associations are now either almost extinct or very inaccessible for study, and this scheme would

bring them within reach of students in the capital city. (3) Illustrations of the horticultural use that can be made of New Zealand plants, by the planting out of small gardens, alpine rockeries, etc. (4) Restoration of the present forest area of Wilton's Bush to its primeval condition. The area is already much modified and invaded by exotic weeds, but could speedily be brought back to its original state by scientific treatment.

DR. COCKAYNE suggests that the plan should be put into operation gradually over a number of years, and that a start could be made at once by procuring from all parts of the Dominion the plants required to build up the complete collection of the flora, and in particular by concentrating on the formation of an alpine garden along the sides of the mountain stream which flows through the bush. He also suggests the transformation of one of the fine cliffs in the gully into a representation of the typical cliff flora of Eastern Marlborough, which is one of the most striking plant associations known in New Zealand. After that the planting of a small kauri forest could be taken in hand, and so, from year to year, one new effect after another could be added until the scheme was completed. The scheme as outlined (*vide* the *Dominion*, Wellington, June 15) appears to us to be a very fine one, and will certainly meet with the cordial support and approval of botanists throughout the world. We hope that the Wellington City Council will take a wide view of the problem and not allow considerations of finance to stunt a plan which, if carried out in a broad and generous spirit, will add greatly to the fame of a capital which at present is perhaps too much renowned for its windiness and too little known for its wonderful beauty.

A PUBLIC demonstration of the potato trials carried out by the National Institute of Agricultural Botany at its Potato-Testing Station at Ormskirk took place on August 11. Research into the resistance of potatoes to wart disease (*Synchitrium endobioticum*), undertaken by the Institute on behalf of the Ministry of Agriculture, forms a large part of the work. Wart disease is fortunately not spreading, but there is an urgent demand from infected districts for improved immune varieties. New productions of breeders are grown by the Institute at Ormskirk in highly infected soil to determine their reaction to the disease. A variety is only certified as immune if it has been grown for at least two years at Ormskirk without showing any trace of disease. Dry seasons do not afford a good test, and therefore occasionally three or even four seasons are required. This year 97 stocks are being tested for the first time, 45 for the second, and 9 for the third. There are also 626 stocks of from two to ten tubers each, which are grown both to inform breeders at the earliest possible date which of their seedlings are susceptible, and to assist genetical studies on the inheritance of immunity. It is of interest to note that it is theoretically possible to find an immune variety as a parent which will produce 100 per cent. immune seedlings, no matter what the other parent is. Research is also made on the methods of transmission of virus diseases, such as leaf-roll and mosaic, which are a serious menace to English potato crops. There appears to be some correlation between the health of the crop from which the seed-tubers are taken and the incidence of these diseases in the following year. On the other hand, the diseases apparently cannot be transmitted through the soil or by mere contact of foliage. Trials are also being made both of the chief main crop varieties and of the best new immunes to determine their yielding capacity and the time taken to mature. The improvement of the methods of testing these characters is also under investigation. Finally, all stocks sent to Ormskirk as new are examined by the Institute's Potato Synonym Committee; 1533 stocks were reviewed between 1920 and 1925. In 1920 72 per cent. proved to be 'synonymous,' but by 1925 this unsatisfactory proportion had been reduced to 16 per cent. of the entries, the remaining 84 per cent. being distinct varieties.

A FOURTH edition of the handbook entitled "Particulars of Meteorological Reports issued by Wireless Telegraphy in Great Britain and the Countries of Europe and North Africa" (M.O. 252) has been issued by the Meteorological Office, Air Ministry (London: H.M. Stationery Office, price 4s. net). It contains full particulars of the meteorological bulletins issued by the various countries. These bulletins are normally issued at least three times a day, and include ordinary ground observations of weather, wind, temperature, humidity, and height of the barometer for a number of places. They also include information about conditions in the upper air, reports from and to ships at sea, and weather forecasts. Full particulars are given of the various codes in use for summarising this information. The area dealt with extends westwards to America, eastwards to Siberia, northwards to Spitsbergen, and southwards to northern Africa. Greenland is also now included. Changes constantly occur in the weather reports issued by radio from different countries, and in order to keep those interested informed of such changes, supplements to this handbook are issued from time to time. This revised fourth edition embodies all supplements issued since the previous edition. The area covered by the weather charts prepared from these messages is shown in a frontispiece. Most of the issues can be received in the British Isles by the use of quite modest receiving apparatus. Purchasers of this work will be informed when amending notices are issued and when a new edition is ready if they notify the Director of the Meteorological Office of their desire to receive this information.

No one can work in the vast field of economic and political science or be engaged in business or trade, without continually feeling the need of some work which will supply in a handy form statistical and other information on any of the numerous topics that go to make up the complexity of modern life.

It is well known that such works—encyclopædias, year-books, professional and trade directories, commercial returns, biographies, and so on—are published in large numbers in all parts of the world and relating to diverse subjects, but it is not always so easy to obtain definite information of their exact nature or to make the most suitable selection to meet any particular want. Dr. Paul Heile has now set out to provide a guide to this wealth of material in his "Nachschlagebuch der Nachschlagewerke für die Wirtschaftspraxis" (Hamburg: Verlag Wirtschaftsdienst G.m.b.H., 5 marks), which he has compiled, using as a basis the collection of the Welt-Wirtschafts-Archiv at Hamburg after a special attempt had been made to make this as representative as possible. The work is comprehensive and is divided into the following sections: general, geographical, commercial substances, directories (again subdivided geographically and by subject), dictionaries, and biography. German works predominate, as is natural, but the other countries are well represented, as a glance at the geographical section shows, and the value of the work is enhanced by annotations where the title is not self-explanatory and by analysis of those entries which cover more than one subject. It is a drawback to its use as a reference book that such details as place of publication and publisher's names have not been given, but it will nevertheless be a valuable guide for business firms in Great Britain and for our growing commercial libraries. The volume contains also a classified list of the 1000 or so current trade and commercial periodicals taken by the library at Hamburg, together with a history of the Institute. The receipt of the work makes us hope that the promised catalogue of the Library of the London School of Economics will not long be delayed.

THE Annual Report of the Mines Branch (Canadian Department of Mines), for 1924 contains a section on investigation of fuels and fuel testing, which throws light on the fuel problem as it occurs in Canada. Experiments are recorded on the production of coke from the coal of the Maritime Provinces. The coke is intended to make Canada independent of imported anthracite. Tests of friability of coke have been worked out. Reports are made of lubricating oils and gasoline marketed in Canada. The distillation of lignite and sub-bituminous coal and oil shale is considered, evidently an anticipation of the time when supplies of liquid fuel will have to be produced at home.

A BIBLIOGRAPHY of meteorological literature prepared by the Royal Meteorological Society with the collaboration of the Meteorological Office (No. 9, January-June 1925) has recently been issued by the Royal Meteorological Society. Since October 1920 the bibliography which previously had been given in the Society's *Quarterly Journal* has been issued as a separate publication in six-monthly parts (price to non-fellows, 2*s*. 6*d*.). A symbol is attached to the title of the work to show in which library the publication has been received. The divisions of the bibliography deal with general meteorology and with various branches of the work, such as temperature, rainfall, and terrestrial magnetism. The publication is helpful to meteorologists in different parts of the world.

THE annual report of the Physical Department of the Ministry of Public Works, Egypt, for 1923–24, has been issued. Dr. H. E. Hurst, the controller, reports continued progress in all departments. In the hydrological service observations are now obtained from 286 rainfall stations, an increase of five on the previous year, and from 82 gauging stations extending from Egypt to Uganda, Kenya and Abyssinia. The daily weather report continues to be published, based on the data from 28 stations in Egypt and the Sudan, five in Europe and two in Palestine. A daily broadcast message is sent out from Abu Zabal at 09·55 G.M.T. Upper-air investigations by pilot balloons from Helwan Observatory continue. Arrears of meteorological publications which accumulated during the War are being fast overtaken, the annual reports up to 1921 being nearly ready. The report contains a full list of the publications of the department.

VOLUME 17 of contributions from the Jefferson and the Cruft Laboratories of Harvard University consists of reprints of thirty-nine papers on physical subjects which have been published in scientific periodicals during the years 1924–5. Nine of these emanate from the X-ray laboratory of Prof. Duane, six from that of Prof. Bridgman, four deal with radio circuits and their properties, and twelve with spectroscopy. In the last group is a paper by Messrs. H. N. Russell and F. A. Saunders directing attention to certain new regularities in the spectra of calcium, strontium, and barium. Almost the whole of the lines of the first two are now identified by the help of new spectroscopic terms comparable in importance with the older terms, but some of them negative. The authors characterise the present notation of spectroscopy as chaotic, and as the result of discussion with other workers suggest that in future the *series* be denoted by Roman capitals, the *system* by an index at the upper left hand giving the multiplicity, and the *component* of a multiple term by a subscript on the right giving the inner quantum number.

READERS interested in early printing should obtain from Messrs. Bowes and Bowes, 1 Trinity Street, Cambridge, a copy of their Catalogue (No. 435) of books printed from 1477 to 1600. The list comprises some 548 titles, to which are added many helpful notes.

THE British Science Guild will publish shortly a Supplement to its Catalogue of British Scientific and Technical Books. The Supplement has been compiled by Miss Daphne Shaw from the monthly lists published in NATURE, and it will contain 2258 titles of books issued in 1925, classified alphabetically from agriculture to zoology, as well as an author index.

MESSRS. Chapman and Hall, Ltd., ask us to state that they have had in active preparation "The Theory and Practice of Radiology," by Dr. B. Leggett, but

that in consequence of a fire at their printers the whole work, almost completed, was destroyed, and it is therefore necessary to recommence production and there will be a delay of some months in the publication of the volume.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned :—A junior inspector of mines in the Mines Inspectorate of the Government of India—The Secretary to the High Commissioner for India, 42 Grosvenor Gardens, S.W.1 (August 30). Assistant masters for, respectively, physics and mathematics and chemistry, and physiology and biology at the Lawrence College, Ghora Gall (Murrer Hills), India—The Principal, St. Luke's College, Exeter (August 31). An adviser in dairy bacteriology at Armstrong College, Newcastle-upon-Tyne—The Registrar (September 2). An assistant bacteriologist in the Department of Pathology and Bacteriology of the University of Sheffield—The Registrar (September 11). A lecturer in plant physiology in the University of Aberdeen—The Secretary (September 14). A senior metallurgist under the British Cast Iron Research Association—The Director, 75 New Street, Birmingham (September 15). A professor of philosophy in the University of Sydney—The Agent-General for New South Wales, Australia House, Strand, W.C.2 (September 15). A professor of psychiatry in the University of Sydney—The Agent General for New South Wales, Australia House, Strand, W.C.2 (September 15). A research bio-chemist at the Walter and Eliza Hall Institute of Research, Melbourne—The Agent-General for Victoria, Victoria House, Melbourne Place, Strand, W.C.2 (September 30). An adviser in agricultural chemistry at Armstrong College, Newcastle-upon-Tyne—The Registrar (October 1). A lecturer in mathematics and physics in the Government College for Indian Women, Lahore—Miss G. Harrison, The Poplars, Buckingham.

Our Astronomical Column.

THE AUGUST PERSEIDS OF 1926.—Mr. W. F. Denning writes that "a series of very clear nights during the first eleven days of August enabled these meteors to be well traced as they gradually increased to a maximum on the morning of August 12. On August 7 the shower was strikingly evident by some fine, flashing meteors. The hourly number observed was about twenty-five from all radiants, of which the proportion from Perseus was sixteen. On August 10, after rain and clouds had prevailed in the early part of the night, the sky became very clear and 60 meteors were seen by an assistant during a watch maintained for $2\frac{1}{2}$ hours. The great majority of these were Perseids and were fairly bright with the normal features of swiftness and afterglows, the latter being strongly marked in several cases where the heads were unusually lustrous. On August 11 clouds and rain again affected the conditions, but soon after 22^h G.M.T. the sky became clear and the ensuing morning presented an ideal aspect for astronomical purposes. A look-out was maintained for $4\frac{1}{2}$ hours and 180 meteors were counted. About 145 of these were Perseids and included a fair proportion of conspicuous objects with long paths and a rapidity of movement which called for celerity on the part of the observer in accurately recording their flights. The maximum of the shower occurred between 2^h and 3^h G.M.T., August 12, when 60 meteors appeared. On the whole, however, the display may be regarded as only of moderate intensity and not nearly so rich in number as those of 1871, 1874, 1877, 1921 or some other years."

SOLAR RADIATION.—Special attention is directed by the Scientific News Service of the Smithsonian Institution to a recent issue of the *Monthly Weather Review* of the U.S. Weather Bureau, which is said to contain a further corroboration by Dr. Abbot of the reality of the variability of the sun's radiation. From a series of observations made at Mt. Wilson by himself and Mr. L. B. Aldrich during the years 1910–1920, a selection has been made of the days on which the atmospheric conditions were as nearly identical as possible, these being divided into comparable groups. Observations made throughout 1912 and 1913 were discarded on account of the Mt. Katmai eruption. When the mean values of the solar radiation readings for these selected days, grouped for a month at a time (the mean value for July of each year from 1910–1920 is given as an example), are plotted, together with the solar constant values already published by the Smithsonian Institution and the sunspot numbers for the same epochs, a close degree of parallelism is shown between the three sets of observations. It is also claimed that short interval changes within the individual months are verified. It is not stated, however, whether the data for other months or periods of the year give as close agreement as that shown for July. The full details of Dr. Abbot's communication will be awaited with interest.

THE SYSTEM OF CASTOR.—This beautiful system became still more interesting when Adams and Joy found in 1920 that the distant companion C (about 1′ distant from the bright pair) was itself a spectroscopic binary. The period was at first given as 4 days, corrected later to 0.815 days. C is of magnitude 9.03; as the two spectra are of equal intensity, each component is of mag. 9.78; taking the parallax as 0.0747″, this corresponds to absolute mag. 9.15.

Mr. H. van Gent, of Leyden Observatory, examined C for variability and found that it is an eclipsing binary. He has determined the light curve from photographs taken with the Leyden 33 cm. refractor. He discusses the observations in *Bull. Astr. Inst. Netherlands*, vol. 3, No. 97. The radius of each component is 406,000 km.; the mass of each is 0.518 sun and density 2.60 sun; the distance apart 2,581,000 km. and inclination 86°.

The surface brightness of each component is 3.31 mag. fainter than that of the sun. The effective temperature is deduced as 3500°, agreeing well with the spectral type *M*. These exact details concerning a red dwarf star are of great interest.

It is noted that Castor C has the greatest parallax and proper motion so far known among eclipsing variable stars, and that the components of 61 Cygni have similar absolute magnitude and colour.

Research Items.

THE HUNGARIAN BRONZE AGE.—In *Man* for August, Dr. Lajos Zoltai describes two bronze hoards from Hajdusámson, near Debreczen. The finest examples of the Hungarian bronze industry come from the region known as the Nyirség in the north-east bend of the Tisza, which would appear to have been densely populated and a centre of culture in the Bronze Age. The hoards here described are now in the City Museum of Debreczen. The first consists of a sword and twelve axes found in an orderly grouping which suggests a votive deposit. The leaf-shaped sword is only 53·2 cm. long and has a pommel of which the button consists of closely fitting superimposed rhombs, diminishing in area from the base, the smallest being pointed. Such a pommel is unique in Hungary but is met in Scandinavian swords. Analogous forms of sword are figured by Montelius from north Germany and north Italy. The scroll decoration of the blade is peculiar to Hungary. Three of the axes are similarly decorated. Hajdusámson lies near the centre of the region in which axes ornamented with this scroll pattern are found. It may be described as the centre of the area of fabrication. The second hoard consisted of a number of bronze vessels of which the peculiarity lay in the double handles and their mode of attachment. Mr. Gordon Childe, in an appended note discussing the chronology of the finds, points out that they illustrate two periods of the Hungarian Bronze Age. The leaf-shaped sword belongs to the earliest variety and, being stamped clearly with marks of local manufacture, supplies a link missing in Peake's argument for the Hungarian origin of the type.

PHYSICAL CHARACTERS OF THE FRANKS.—A detailed study of skeletal remains from a Franco-Merovingian cemetery at Baye (Marne) by M. H. V. Vallois in Fasc. 4-5-6, Vol. 6, VII^e Série of the *Bull Soc. d'Anthropologie de Paris*, concludes with a comparative study of such material relating to these invaders of France as is available. The typical Franks would appear to be comparable to the tall dolichocephals of the *Reihengräber*. The type is found with some frequency in Flanders, but in France it rapidly merges into the rest of the population. Thus the Frankish cemeteries of the centre and east of France show a fairly homogenous population in which the skeletal characters agree, generally, with those of the Franks of Belgium, in being dolicho- or sub-dolichocephalic, mesoseme, mesorrhine, or leptorrhine, to some extent prognathous and with a marked protuberance of the occiput. But in the south of Belgium and the more central parts of France these characters rapidly undergo progressive modification, dolichocephaly becomes sub-dolichocephaly, leptorrhiny, mesorrhiny, and the effect of crossing with the Gallo-Roman populations is more and more marked as the distance from the Frankish centre of origin increases. The decrease in stature is considerable, and the measurements given here, 1·64-1·67 m. (males), 1·53-1·58 m. (females), while higher than those of the neolithic peoples, do not exceed those of the Gauls or medieval or modern Parisians. It is noted that while the early crania are predominantly dolichocephalic, and brachycephals are rare, the face being long and narrow of the typical Nordic character, in the cemeteries of Normandy by Merovingian times the dolichocephals are becoming more rare and are mixed with brachycephals, and by the tenth and eleventh centuries the brachycephals are almost the only type, showing that by then the original Gallo-Roman population had resumed preponderance. Yet it is remarkable that while the tall stature and leptorrhiny disappeared almost at once, dolichocephaly, prognathism and the protuberance in the occipital region persist for a much greater length of time.

MODERN WHEAT BREEDING.—The aim and present position of modern wheat breeding is outlined by Sir Rowland Biffen and F. L. Engledow in *Research Monograph* No. 4 of the Ministry of Agriculture and Fisheries. So far as possible the account is couched in non-technical language to render it intelligible to farmers and other non-academic readers, and it presents a clear and concise picture of the methods adopted and the results attained. After a general statement of the problem the principles of heredity and various theories bearing thereon are discussed, together with the complications associated with linkage, chromosomes, races and species. Breeding may be for increased yield or better quality of grain, for greater resistance to disease or for straw less liable to lodging, and in each case specific methods have to be adopted. Increased strength of straw is a most important point, as in many cases farmers are afraid to cultivate in such a way as to obtain the maximum possible yield, for fear lest the crop should lodge and the expense of the extra cultivation and manuring be lost without adequate return. The process of breeding new cereals is necessarily slow, since, owing to the rigid tests that are needed for purity for milling and baking, about ten years must elapse before any promising new variety can be placed on the market. The need in British farming is for a strong wheat with good yielding capacity, and in 1916, Yeoman wheat was introduced to meet these demands so far as possible. After several years' further experiments a still better wheat has been produced, known as Yeoman II., and it now remains to be seen whether this will fulfil its promise under ordinary methods of general cultivation.

HERRING, MACKEREL, AND PLANKTON.—Many naturalists have expressed the belief that movements or occurrences of herring and mackerel at certain seasons are influenced by the presence or absence of certain planktonic organisms. If this is so, then fishermen might benefit greatly by an instrument which would give them a quick indication of the state of the water in which they were proposing to fish. An instrument for use on commercial fishing craft must, however, be simple, strong, easily handled and rapid to use. In his paper, entitled "The Herring in Relation to its Animate Environment," Part 2 (Min. Agric. and Fish., Fishery Investigations, Ser. 2, Vol. 8, No. 7. London, H.M.S.O., 1925), Mr. A. C. Hardy describes trials of his 'plankton recorder,' which consists essentially of a cylinder carrying a white gauze filtering-disc. When the instrument is towed end-on through the water, plankton is deposited on the disc, imparting to the latter a distinctive colour which is dependent on the nature and number of the plankton organisms present. Discs used from commercial drifters in 1922 and 1923 during the herring fishery in the North Sea, and the south-west mackerel fishery from Newlyn, strongly suggested that poor fishing occurred in waters which gave a green disc (due to the predominance of Diatomacea or Phaeocystis). On the other hand, no very convincing correlation could be demonstrated between the number of copepods (red, pink or yellowish-pink disc) and the quantity of fish caught. Confirmation of the results of these preliminary trials is needed, and much interesting and useful information may be expected from an extensive use of this plankton recorder.

FISHERIES INVESTIGATIONS IN DENMARK.—The report of the Danish Biological Station for 1925 covers a wide range of work. Dr. Petersen, in a short discussion on the influence of fishing upon the stock of plaice in the Baltic, gives figures, based on official statistics of landings, which show that since the War there has been a steady decrease in the annual yield of plaice in that region. He suggests that the time has come for a suitable protection of plaice in the Belt sea, and, if possible, by the aid of international legislation, also in the Kattegat and certain parts of the Baltic. A report on the estimation of the density of oyster-population in the Limfjord gives instructive data of collections made by divers. In 1907 the density was estimated to be 1 oyster for each 3·2 square metres, but in 1924 it had dropped to only 1 oyster for each 38 square metres—a reduction to $\frac{1}{12}$. In addition to living oysters, the diver collected the shells of dead individuals. The shells of oysters which had died since the previous summer were easily recognisable, and thus an estimate could be made of the mortality during the season 1923–1924. An alarmingly heavy death-rate of 71 per cent. of the stock was indicated for the hard bottom area in the western parts of the Broad of Livo. Dr. Blegvad gives an account of his continued studies on the quantity of fish-food in the sea bottom, by means of the Petersen bottom sampler, and the detailed examination of the stomach contents of fishes. He attributes the considerable variations in quantity of food for fishes, from year to year, to (1) good brood years of the chief food species, alternating with bad years; (2) the consumption by fishes and other predatory animals, although the effect of the consumption by fishes has probably been exaggerated; (3) physical reasons, such as cold and lack of oxygen, which often kill off large numbers of food animals, especially during the winter.

FERTILITY IN THE DOMESTIC FOWL.—Dr. F. A. E. Crew gives (*Proc. R. Soc. Edin.*, vol. 46, pt. 2, 1926) the results of a series of experiments designed to determine the time of the onset of fertility in the domestic hen after the introduction of the male and the duration of fertility after his removal. He found that fertile eggs can be expected within 24-48 hours after the introduction of the male, though the onset of fertility varies with different matings. The length of life of the sperm within the body of the female is 15-20 days, but the eggs laid after the first week commonly fail to complete their development. If after the removal of the male a second male is introduced, the influence of the first sire is removed by the seventh-tenth day and there appears to be a relation between the general vigour of the male and the fertilising power of the sperm it produces. These results have an important practical bearing for the poultry farmer.

THE ANATOMY OF THE ELEPHANT.—Dr. N. B. Eales has made a careful and detailed dissection of the head of a fœtal elephant and has given an account of her results (*Trans. R. Soc. Edin.*, vol. 54, pt. 3, 1926) illustrated by twelve plates of beautifully clear and well-executed drawings. The work amplifies and corrects that of earlier workers and, as the specimen is unique, Dr. Eales has made the fullest possible use of it. The most interesting result obtained by the author is the evidence of ancestral history revealed by the characters of the lower jaw. The upper part of the skull is essentially like that of the adult and of all modern elephants, the differences being due to fœtal characters entirely. But the lower jaw exhibits the *longirostris* phase of the modern elephant's ancestry. It is relatively longer than in the adult, and the change to the adult condition is accompanied by a definite metamorphosis involving a relative shortening of the anterior part of the mandible. This interesting observation is of the utmost importance as corroborative evidence supporting the accepted facts of palæontology. Dr. Eales is to be congratulated on the completion of a distinguished piece of work.

CULTIVATION OF DROSOPHILA FOR LABORATORY PURPOSES.—Drosophila is now widely used as a laboratory animal especially in genetic investigations, and there is no reason why it should not be used extensively for class purposes to demonstrate the most important results of modern research in genetics, provided it can be kept successfully in the laboratory. With this end in view Prof. Raymond Pearl has investigated the possibilities of making a satisfactory synthetic food medium, free from the uncertainties of the standard banana medium now in use, which would give the required degree of quantitative precision desirable in genetical work. Such a medium is described in a recent paper by Prof. Pearl (*Journ. Gen. Physiol.*, March 1926, vol. 9, No. 4). It is an entirely artificial medium, containing no natural fruit juice and with a higher degree of acidity than the banana medium. On account of its high acidity there is practically never any contamination of the cultures by troublesome bacteria. Experiments with this medium have shown that it is greatly superior to the banana medium in respect of both the fertility and the mortality of the flies kept on it. These results should be of great service to laboratory workers and teachers who may wish to keep Drosophila for class purposes.

YIELD AND POSITION OF FIELD CROPS.—The effect of outside rows on the yields of kafir and milo crops has been determined by J. S. Cole and A. L. Hallsted in the United States over a period of eight years (*Jour. Agric. Research*, 32, 10). The outside rows of 10-row plots gave heavier yields than the inside rows except in 1915, a year of unusually low temperature and heavy rainfall. The increase was much greater in the yield of grain than of stover. On an 8-year average, the acre yield of kafir grain from the outside rows was 30 per cent. higher than that from the inside rows, but the stover was only 7·5 per cent. higher. With milo the figures were 43 per cent. excess grain and 8 per cent. excess stover in favour of the outside rows. The increased yield of grain from the latter proved to be roughly proportionate to the increased area of soil available to them. The relationship between the yields from all ten rows and the inside eight rows of each plot proved to be linear, the correlation being very nearly perfect, and consequently the relative merits of the methods represented could be equally well determined by either including or rejecting the outside rows. The yields determined from the entire 10 row plots were, however, subject to a systematic error arising from the fact that the effective areas of the plots were somewhat greater than the conventional areas assigned to them in converting the plot yields to acre yields.

A NEW SPHYGMO-MANOMETER.—Messrs. Hawksley and Sons, Ltd., 83 Wigmore Street, London, W. 1, have submitted to us for inspection a specimen of the 'Baumanometer' devised by Messrs. W. A. Baum and Co. Inc., New York, for the measurement of arterial blood pressure. The instrument is a modified form of the well-known mercury sphygmo-manometer. To justify the introduction of still another instrument

for measuring blood pressure the booklet supplied with the instrument finds two faults with the existing U-tube manometer, namely, the smallness and variability in the bore of the tube. It states that errors so great as 20 mm. may occur with the old pattern. We are not aware that such an error could be possible, especially as we know in Great Britain that the pressure depends merely on the difference in level in the two limbs of the U-tube, the capillarity effects being negligible. This head of pressure is independent of the shape and course of the intervening tube, and the exhortation by the makers to the physician "to admit his shortcomings on the mechanical side and review his elementary physics" might well be reciprocated. The desk-model submitted to us has a good appearance and is a well-finished instrument. The U-tube consists of a tubular left limb (bore $\simeq$ 0·5 cm.) and a much wider right limb (bore $\simeq$ 2 cm.). The change of zero is compensated for by graduating the left limb in 'calibrated millimetres.' The shift and disregard of the right limb reading also necessitates the bore of the left tube being taken into account, which we find has been done. The instrument possesses two definite advantages which will be appreciated by the busy clinician, namely (1) the wider left bore prevents air pockets and (2) the scale divisions ($\simeq$ 0·9 mm.) are easier to read and only the left limb has to be read. It must be pointed out, however, that the scale calibration stressed in this instrument has become necessary owing to the makers' deviation from the usual simple manometer with uniform bore and double reading. Further, the great increase in size of the bore of the tube involves a corresponding increase in the inertia of the moving mercury and consequent damping of oscillations.

MAGNETIC ALLOYS.—Mr. P. E. Billinghurst, writing from Camp Mizine, Salween River, Burma (c/o Messrs. Thomas Cook and Son, Rangoon), points out that if the atomic weight of each constituent of Heusler's alloy is multiplied by the fraction by weight of the element present and the sum taken, it is equal very nearly to the atomic weight of iron. He states that he has produced a number of similar magnetic alloys containing gold, bismuth, tin, silver, copper, and zinc, and found that the above relation holds for them equally well. Owing to the loss of his records by fire he is unable to give the actual figures.

LENGTHENED CHAIN COMPOUNDS OF SULPHUR.—We have received the advance proof of a paper on lengthened chain compounds of sulphur by P. C. Rây and K. C. Bose-Rây which is to be published in the *Journal of the Indian Chemical Society*, vol. 3, No. 2. According to V. Meyer, dithioethylene glycol reacts with ethylene bromide to give a mixture of 1 : 4 dithian and its polymer, the product varying according to the conditions. The polymer has been investigated by the authors and found to consist of a mixture of brominated long-chain compounds, including the substance $BrC_2H_4(S\ .\ C_2H_4)_{48}Br$, which is the first example of an organic sulphur compound with a molecular weight so high as 3068.

CADMIUM PHOTO-ELECTRIC CELL.—A cadmium photo-electric cell has been designed by Messrs. H. D. Griffiths and John S. Taylor to measure ultra-violet radiation of the range of wave-lengths which are of therapeutic importance. It consists of the cell itself, in which cadmium forms the active element, and a simple electroscope. The cadmium is deposited by distillation on a plate in front of which is a grid insulated from the plate. The radiation is admitted through a quartz plate and the cell is filled with hydrogen at a low pressure. In use, the grid is charged positively and thus attracts the electrons released from the illuminated plate. The instrument was found very sensitive to unscreened radiation from a quartz mercury lamp. By the use of various filters, it was found that visible and ultra-violet radiation of a wave-length longer than 3500 Å. had no appreciable effect on the instrument. There was no fatigue to be detected during a prolonged exposure. The instrument is sold by Messrs. Watson and Son, Ltd.

WAVE-LENGTH AND THE PHOTO-ELECTRIC BEHAVIOUR OF CRYSTALS.—In the *Zeitschrift für Physik* of July 12, Messrs. B. Gudden and R. Pohl direct attention to the apparent antagonism between the action of long and short wave-lengths when photo-electric absorption of light takes place in solid bodies. They show that it is not due to any real difference between the specific behaviour of the different waves. The essential effect of all wave-lengths is to split off electrons from the atoms, and the observed phenomena can be explained by assuming, in agreement with the experimental results, that a space element of the lattice is only able to support a definite maximum disturbance due to the photo-electric splitting off of electrons, the value of this maximum depending on the temperature. When the maximum is reached, a kind of breakdown takes place and the excited centres go back to their original unexcited state. The disturbances cause a widening of the spectrum on the long wave-length side, similar to that caused by thermal movements or lattice defects. The disturbances vanish as soon as the extra long wave-length light absorbed owing to the above widening has split off enough electrons to increase them above the critical limit.

RESISTANT STEELS.—A paper communicated to the recent Congress of Chemists in London by Messrs. T. G. Elliot and G. B. Willey, dealt with various types of steel now produced commercially by Messrs. Hadfields, Ltd., having great resistance to high and to low temperatures and to attack by chemical agents. The steels are of the austenitic type, and are characterised by high ductility, and by a tensile strength which is retained at high temperatures, one of them giving a value of 31 tons per sq. in. at 700° C. The creep test is even more important than the ordinary tensile test, as it indicates the stress at which a heated mass of the metal could stand for an indefinite time without change of form. The steel in question has a creep stress of so much as 11 tons per sq. in. at 700°. Alloy steels of this class also resist both scaling and warping when heated for long periods in air and subjected to rapid heating and cooling, so that they find a wide application as furnace fittings, hardening boxes, recuperator tubes, etc. Another variety, apparently differing somewhat in composition, is used for turbine blading. A third is used in low-temperature plant, retaining its ductility even in liquid air. For example, a Frémont shock test figure of 50 kg.m. has been obtained at − 195°, mild steel only giving 3 kg.m. The paper contains numerous figures relating to mechanical tests, and records of performance in use, including resistance to acids and other corrosive substances, a field in which so much progress has been made in recent years by the introduction of steels highly alloyed with nickel and chromium. The greater initial expense of such steels, and the greater difficulty of working them, are offset by the very greatly increased durability under the conditions to which the steels are exposed in chemical works and elsewhere.

The International Geological Congress at Madrid.

THE fourteenth session of the International Geological Congress was held in Madrid towards the end of May last. It was presided over by Señor D. César Rubio y Muñoz, under the honorary presidency of His Majesty King Alfonso. Señor Rubio is the President of the Board of Mines and was formerly President of the Geological Institute, entrusted with the preparation of the geological map of Spain. His successor, Señor D. Domingo de Orneta, who was to have taken an active part in the meeting, died shortly before it was held.

The Geological Congress is almost the sole survivor of the scientific congresses which formerly played such an important rôle in international scientific comity. It is still open to men of science of all nations, a distinction to which the scientific unions constituted under the International Research Council can lay no claim.

After a preliminary meeting of the Government delegates on the previous day, the congress was formally inaugurated by the King on Monday, May 24. The total number of members was more than a thousand. Many of these had already taken part in excursions to the Canary Islands and Morocco, or to Huelva, famous for its cupriferous pyrites, or other places of geological interest in the south of Spain. Toledo, Aranjuez, Almaden with its mines of mercury, and the Guadarrama mountains that separate Old from New Castile were visited during the meeting, and afterwards there were other excursions to the Balearic Islands, the potash deposits in Catalonia, the Pyrenees, the important coalfield of Asturias, and the iron ores in the neighbourhood of Bilbao.

The Spanish Government and the municipalities of Madrid and of the towns that were visited in the excursions extended splendid hospitality to the members of the Congress There was a Royal reception at the Palace, a gala theatrical performance, a municipal garden party, and a banquet at which the speeches, twenty-seven in number, commenced with the fish course. This was followed by a charming exhibition of national costumes, dances, and singing, in which the performers were all amateurs

In spite of these attractions, time was found in the different sections of the Congress for valuable discussions on matters of current geological interest.

There were a number of contributions on recent physical methods of studying the configuration and economic possibilities of the rocks of particular areas by electric, magnetic, and gravimetric methods, and observation of the propagation in the earth's crust of artificially produced vibrations.

The pyritic deposits of the south of Spain, to which reference has already been made, were the subject of important papers, and the greater part of two days was devoted to the discussion of the question as to whether they were formed by replacement or owed their origin to magmatic or pneumatolytic intrusion or deposition. Considerable attention was also given to the part played by Hercynian and Alpine movements in mountain building, more especially in Spain.

Perhaps, however, what was of the greatest interest to the British representatives was the consideration of questions of African geology in connexion with the proposed international geological map of Africa on a scale of one in five million, which was resolved on at the previous Congress at Brussels in 1922. A number of representatives of British African surveys were present as well as those of France, Belgium, Spain, Portugal, Italy, and Egypt. It was gratifying to note the progress that has been made in the interval. A geological map of the whole of South Africa has been recently published on a scale of one in one million, and one of Egypt on a scale of one in two million, and of South-West Africa on the same scale. Maps of the Anglo-Egyptian Sudan and Somaliland on a scale of one in three million, of the Gold Coast on one in one million five hundred thousand, and Gambia on one in five hundred thousand, and of all the remaining British African colonies or mandated territories, Nigeria, Uganda, Kenya, Tanganyika, Nyasaland, British Bechuanaland, and Northern Rhodesia, as well as of Southern Rhodesia, on a scale of one in two million, have been prepared, and work on other parts of Africa is well advanced. The map of the whole of Africa on the scale of one in five million will be prepared under the auspices of the Belgian Government as soon as all the materials are ready.

Of permanent value as a conspectus of the geology of Spain are the excellent guides, some nineteen in number, to the excursions. Many of them are published not only in Spanish but also in French, English, or German, or more than one of these languages. At the same time the Municipality of Madrid presented the members of the Congress with a well-illustrated volume on the Quaternary rocks of the Manzanares Valley by José Péres de Barradas.

The greatest achievement of the Congress, however, was the re-creation among geologists from all parts of the world of the atmosphere of friendliness and cordiality that prevailed in the days, which now seem so remote, 'before the War.'

Cancer Causation: Importance of Cell Physiology.

IN an interesting paper read before the German Chemical Society, at the meeting recently held at Kiel, Dr. Otto Warburg said that the attempts made artificially to produce carcinoma by tar-painting or by X-ray radiation showed that the normal tissues contain cells in which carcinoma may begin without help from any outside cells or micro-organisms. There is no cancer bacillus, just as there is no diabetes or arteriosclerosis bacillus The cancer problem is a problem of cell physiology in the narrow sense, and limited to the physiology of the body cells.

Since cancerous tissue grows differently from normal tissue, that is to say, irregularly and to excess, it follows that the metabolism of the cancer cell differs from that of the normal cell. Since, on the other hand, the carcinoma cell as an actual body cell originates from normal cells, it becomes necessary to correlate carcinoma metabolism with normal metabolism. Like normal organs, the tumour consumes oxygen and gives off carbon dioxide; the veins of the tumour contain less oxygen and more carbon dioxide than the arteries. Like normal organs the tumour requires glucose, and its veins contain less glucose than the arteries. But, unlike the normal organs, the tumour produces lactic acid which is passed into the blood, a portion of this acid being obtained from the blood sugar, which the tumour to a certain extent oxidises in the same way as normal organs, but for the most part splits into lactic acid. Careful research has shown that there is lactic fermentation of the glucose, and in fact there are a large number of different kinds of malignant tumours, for example, transplanted rat

carcinomata and sarcomata, the Peyton Rous chicken sarcoma, tar carcinoma in rabbits, and all kinds of human cancers, which qualitatively and almost quantitatively show the same result. We have here, therefore, a general characteristic of carcinoma and sarcoma cells which is entirely independent of any particular kind of irritation or of the nature of the normal tissue in which the tumours originate.

If, now, it be asked in what manner tumour metabolism arises out of normal cellular metabolism, it is necessary to inquire first of all under what conditions normal cells split glucose into lactic acid. Normal body cells produce lactic acid when their respiration is inhibited, either by cutting off the supply of oxygen or by poisoning. The production of lactic acid from glucose is, therefore, no peculiar property newly acquired when tumours first form, but is a property common to all body cells. But whilst in normal cells lactic fermentation is only set up by absence of oxygen, tumour cells always produce lactic acid, even when they are fully supplied with oxygen.

The results of these investigations may therefore be summed up in the statement that the tumour, so far as its metabolism is concerned, always behaves as a normal growing cell in a state of asphyxia. If normal growing cells be deprived of oxygen, then we have the reaction of a carcinoma cell. Since by deprivation of oxygen respiration is inhibited, fermentation cannot be masked or prevented, and the asphyxiated cells continue to produce lactic acid in excess, even when the oxygen supply is restored. Most of the cells so treated die because they are unable to live at the expense of energy of fermentation. Only a small number of them remain alive, and in their nature, magnitude and action they are indistinguishable from carcinoma cells.

Dr. Warburg then considered the question whether the asphyxia of normal growing cells sufficed to bring about the cancerous state, or whether other unknown factors also played a part. Reference was made in this connexion to the recent experiments of Carrel, Dresel and Wind, in which the attempt was made to discover whether carcinoma cells can not only exist without breathing, through energy of fermentation, but can also grow. The general conclusion was that tumour cells, like yeast, cannot live their full period without oxygen, but that both kinds of cells are able to grow for a time without oxygen, by the energy of fermentation, and that the asphyxiation of normal growing cells is sufficient to produce the cancerous state

Hæmoglobin.

HÆMOGLOBIN, the oxygen-carrier in the blood of vertebrates, upon which life depends, is a substance of great interest and importance, the investigation of which has received considerable attention from research workers. Prof. J. Barcroft, whose lecture on hæmoglobin, delivered before the Chemical Society on February 11, 1926, has been published in the Society's journal for May 1926, gives an account of recent investigations on the subject.

The old idea that hæmoglobin is a compound of two bodies, called *hæmatin* (containing iron) and a protein, *globin*, is not altogether untrue The well-defined crystalline substance *hæmin* is obtained by the action of glacial acetic acid on dried blood. When hæmin is oxidised in the presence of alkali, hæmatin is obtained. Alkaline reduction of hæmin yields *hæm*, a substance having an ill-defined spectrum. Nicotine, pyridine, globin, etc., when added to hæm, produce a class of substances with well-defined and similar spectra, called *hæmochromogens*. Of these it appears that the globin compound alone can form a hæmoglobin by regulation of the hydrogen-ion concentration. Cytochrome, another substance well known to the biochemist, has been proved by examination of the absorption spectrum to consist of three hæmochromogens.

The determination of the equilibrium constant K for hæmoglobin and oxygen and for hæmoglobin and carbon monoxide by the ordinary methods of gas analyses is exceedingly difficult on account of the low pressures of the gases involved, and methods have been worked out which involve spectroscopic measurements. The velocity constants, k and k', for these reactions have been obtained by an ingenious form of apparatus which overcomes the difficulties due to the high order of velocity by very rapid mixing of the components. For the reaction $HbO_2 \longrightarrow Hb + O_2$, k' is relatively small, whereas the constant for the formation of the oxide is very large and is also comparatively independent of the temperature and hydrogen-ion concentration. It follows that the equilibrium constant, $K = k'/k$, must be a measure of the effect of the reduction phase. Parallel observations with carbon monoxide show that the slow-reduction phase in the case of oxygen is peculiar.

There is a shift towards the blue in the position of the important α-band in the absorption spectrum when the hæmoglobin is treated with carbon monoxide. This shift, measured in Ångström units, is called the 'span,' and a nearly linear relation is obtained between log K and the span of hæmoglobins from various sources, where $K[HbO_2] \times [CO] = [HbCO][O_2]$. This is supposed to indicate that "there are a limited number of hæmoglobins, say two, which in different animals are mixed together in different proportions." The difficulties encountered in the measurement of osmotic pressures are also considered and in conclusion attempts are made to reconcile the equation, $Hb_4 + 4O_2 \rightleftharpoons Hb_4O_8$, which these measurements indicate, with the shape of the equilibrium curves previously obtained.

Contact Catalysis.[1]

THE Committee on Contact Catalysis under the chairmanship of W. D. Bancroft has performed an excellent piece of work in collecting together and commenting upon the interesting peculiarities of surfaces in affecting the rates of chemical change of reactants at, or in close proximity to, those surfaces. Whilst certain purists may object to the term 'contact' in connexion with reactions the velocities of which are accelerated by the presence of substances which, although taking part in the chemical change, are not present either in the reactants or products in stoichiometric quantities; yet the word possesses advantages in differentiating homogeneous reactions from reactions heterogeneously accelerated.

In the United States, Dr. H. S. Taylor himself has been largely instrumental in stimulating interest in problems in this field, which during the last decade has attracted an increasing number of research students in all countries, and from which a remarkable crop of new technical industries, not without economic value, has already been harvested.

In 1917 Langmuir showed that chemical reaction

[1] Fourth Report of the Committee on Contact Catalysis. By Hugh S. Taylor. *Jour. Phys Chem.*, xxx, 145, 171, Feb. 1926.

was probably restricted to the molecules of the reactants actually in contact with the surface. Whilst the experiments of Bone and others at high temperatures indicate that this generalisation may not be always true, yet in a large number of reactions such appears to be the case. Even in combustion at hot surfaces, reaction chains may start from, or, electrons or ions which in turn effect reaction may be emitted from the surface. Four years later it was shown simultaneously in England and the United States that the whole of a surface could not be equally uniform in affecting the rate of chemical action, certain portions of the surface being more active than others. Data both on the quantities and heats of adsorption of gases and vapours as well as the effect of poisons on the rate of catalytic action have amply confirmed the theory of active patches, as is shown in the present report.

It is clear that the existence of active patches is due to the fact that the surface of the catalyst is not uniform, but composite, consisting of various planes, corners and edges of minute crystals in addition to atoms isolated on planes and edges as well as atoms in the planes and edges. The work of Born and Lennard Jones on the surface energies of heteropolar compounds leads us to hope that the surface energies of the various portions of a composite metal surface may in time be computed. Only in the case of certain charcoals and of nickel do we possess any definite information on the extents and specific activities of various patches of different activities, but further information on this subject as well as the variation in relative areas will doubtless be forthcoming.

When we are in possession of data on the variation of the surface forces with chemical reaction rate taking place at the surface, some clue may be given to the mechanism of chemical activation, the elucidation of which is stimulating at the present time a renewed interest in the study of photochemistry.

It is to be hoped that such reports may be continued although the labour involved may render their appearance less frequent in future. Both the committee and Dr. Taylor are to be congratulated on this successor to the three reports already published.

ERIC K. RIDEAL.

University and Educational Intelligence.

CAMBRIDGE.—Mr. C. P. T. Winckworth, Christ's College, has been elected Eric Yarrow lecturer in Assyriology. Dr. C. L. Withycombe has been elected University lecturer in advanced and economic entomology. Prof. B. M. Jones has been nominated as a member of the Advisory Committee on Aeronautical Education. Dr. J. L. Witts, University of Manchester, and Mr. J. O. W. Bland, Jesus College, have been elected John Lucas Walker students in pathology. A grant of 100*l*. has been made from the Balfour Fund to Dr. H. Scott, Trinity College, towards the expenses of an expedition to Abyssinia. Mr. H. G. Cannon, Christ's College, and Miss S. M. Manton, Girton College, have been appointed to the University's table at the laboratory of the Marine Biological Association at Plymouth. An industrial bursary has been awarded by the Royal Commissioners for the Exhibition of 1851 to C. Salter, St. Catherine's College.

An interesting report has been published by the Appointments Committee giving a list of all the teaching appointments made under the new statutes and the grants made to the different faculties and departments from the Government grant. The total amount of new grants already thus allotted is 18,710*l*., out of 20,000*l*. available for the purpose.

The following have been elected to research studentships: W. J. Dann at Trinity College; B. C. Saunders at Pembroke College; W. A. Waters (chemistry), R. V. Thomas (chemistry), E. G. Jones (economics), J. G. Adshead (mathematics), H. Stayt (anthropology), T. E. Allibone (physics), and W. R. Wooldridge (biochemistry) at Gonville and Caius College; G. H. Aston, A. Caress, O. H. Wansbrough-Jones and B. J. Wood at Trinity Hall; J. Hilton at Christ's College; J. H. Ratcliffe at Sidney Sussex College; G. E. Watts has been elected Charles Kingsley bye-fellow at Magdalene College.

Further details are now available of the will of the late Dr. J. E. Bles, whose bequests to the University of Cambridge have already been referred to in these columns. He left all his scientific instruments, scientific books, and the fittings and contents of his private laboratory to the University of Cambridge, and he empowered his trustees to expend a sum, not exceeding 500*l*., in completing any researches made by him and publishing the results of any researches not published at the time of his decease. The value of his estate was 42,677*l*.; failing issue, and subject to his widow's life interest and after certain bequests, he left the residue of his property to the University upon trust for a professorship of animal embryology to be called the Charles Darwin professorship, for research and teaching in the subject from a purely scientific aspect; apart from economic, technical, or medical aspects, and subject thereto upon similar terms for a professorship of bio-physics. In the event of these chairs being already constituted, the legacy would have been devoted to the promotion of biological science and subject to a board consisting of the professors of biological subjects, which is also to examine the position of the fund every twenty-five years.

THE Calcutta University Poverty Problem lecturer, Captain Petavel, has for several years been carrying on a campaign of advocacy of a scheme for establishing near Calcutta a co-operative colony of middle-class 'home-crofters,' and in connexion therewith a school of which the pupils would "be systematically organised to produce their food by their own labour, the work being made instructive for them." In his magazine *Bread and Freedom* for July, he announces that a Mr. K. K. Dutta, a well-known Calcutta attorney, has placed at the disposal of his organising committee a village and farm, while another member of the committee has promised to contribute a sum of 10,000 rupees towards a fund for putting the scheme into operation "on business lines." A somewhat similar scheme was recently advocated by Prof. J. W. Scott, of University College, Cardiff.

FROM Loughborough College, Leicestershire, we have received a calendar for 1926-27, giving very fully detailed and illustrated descriptions of the College laboratories and courses in engineering and in pure and applied science including chemical technology. The College has also a Department of Administration and Economics, an Extra-Mural Department, a school of Industrial and Fine Art, and a secondary school for boys. The Faculty of Engineering is noteworthy for its system of concurrent theoretical and practical training, made possible by the large scale of the workshops, half the student's time being spent in productive work. The governors award annually five scholarships in the Faculty of Engineering, each of the value of 75*l*. per annum, open to British subjects in any part of the Empire. Candidates resident outside Great Britain can be examined at local centres.

Contemporary Birthdays.

August 20, 1860. Sir William Henry Ellis, G.B.E.
August 21, 1866. Sir Gerald P. Lenox-Conyngham, F.R.S.
August 21, 1858. Mr. Charles T. Heycock, F.R.S.
August 23, 1875. Prof. W. H. Eccles, F.R.S.
August 25, 1851. Sir John A. F. Aspinall.
August 25, 1844. Sir Thomas Muir, F.R S.
August 26, 1863. Mr. Edward Heawood.
August 26, 1873. Prof. William A. Osborne
August 26, 1860. Sir Thomas Ranken Lyle, F.R.S.

Sir WILLIAM ELLIS is president of the Institution of Civil Engineers, and a past president of the Iron and Steel Institute. He was master cutler of Sheffield from 1914 until 1917.

Sir GERALD LENOX-CONYNGHAM, reader in geodesy in the University of Cambridge, was educated at Edinburgh Academy, afterwards entering the Royal Engineers branch of the army. He was superintendent of the Trigonometrical Survey of India from 1912 until 1921. Sir Gerald is a member of the National Committee for Geodesy and Geophysics of the International Research Council

Mr. HEYCOCK, mathematician and metallurgist, is a fellow of, and lecturer in natural science in, King's College, Cambridge He was president of Section B (Chemistry) at the Cardiff meeting of the British Association in 1920. Mr. Heycock was awarded the Royal Society's Davy medal in that year on the ground of his researches in physical chemistry, more especially on the composition and constitution of alloys. While his work added to theoretical conceptions, it proved of importance also to industrial metallurgy.

Prof. ECCLES was born at Ulverston, Lancashire. He was the last dean and professor of applied physics in the City and Guilds of London Technical College, which was recently closed. Lately president of the Radio Society of Great Britain, he was, last month, elected president of the Institution of Electrical Engineers.

Sir JOHN ASPINALL was born at Liverpool. He was chief mechanical engineer of the Lancashire and Yorkshire Railway from 1886 until 1899. In 1919 he was appointed consulting mechanical engineer to the Ministry of Transport. Sir John is a past president of the Institution of Mechanical Engineers and of the Institution of Civil Engineers.

Sir THOMAS MUIR, for a long period—1892 until 1915—superintendent-general of education in Cape Colony, was born in Scotland. A graduate of the University of Glasgow, he was, early in his career, assistant professor of mathematics there. In 1883 the Royal Society of Edinburgh awarded him the Keith gold medal for his researches into the theory of determinants and allied questions. The unusual course was taken of allotting the medal again in 1897 for continued work in the same field, and once more in 1916 to mark the completion of the series down to 1915, all the memoirs having been published by the Society. Sir Thomas remains faithful to residence in Cape Colony.

Mr. EDWARD HEAWOOD is known to a wide circle as the accomplished librarian of the Royal Geographical Society, a post he has filled since 1901. Born at Newport, Shropshire, he was educated at Queen Elizabeth's Grammar School, Ipswich, graduating at Gonville and Caius College, Cambridge.

Sir THOMAS LYLE was born at Coleraine, Ireland. He graduated at the University of Dublin. From 1889 until 1915 Sir Thomas was professor of natural philosophy in the University of Melbourne.

Societies and Academies.

ROME.

Royal Academy of the Lincei, June 3.—Leonida **Tonelli**: The quadrature of surfaces.—A. **Bemporad**: The astrographic catalogue of Catania.—Ferruccio **Zambonini**: The presence in the products of the present-day activity of Vesuvius of a cæsiferous variety of potassium fluoborate. For a crystalline sublimate from Vesuvius, consisting of potassium and cæsium fluoborates in isomorphous mixture, the name 'avogadrite' is proposed.—Luisa **Pelosi**: Certain geometrical maxima and minima.—Mauro **Picone**: The singularity of harmonic functions.—Oscar **Zariski**: The impossibility of resolving parametrically by radicals an algebraic equation $f(xy)=0$ of the genus $p>6$ with general moduli.—Umberto **Crudeli**: Models of the helium atom.—R. **Mazet**: Oscillations of a liquid in connected vessels.—Vasco **Ronchi**: The limit of resolution of spectroscopic apparatus. The expression 'resolving power' of a prism, grating, etc., is shown to be inaccurate, since such apparatus is characterised only by dispersion. The resolution depends on the means by which it is examined and, when diffraction images are observed, is only one-half as great as when interference images are employed.—Mario **Picotti**: The results of the physico-chemical researches carried out on the Royal Italian cruiser *Marsigli* in the Straits of Messina. Observations on the temperature and salinity of the water are described.—Fausta **Bertolini**: Conformation of the stomach of the Teleostei in relation to the nutrition —M. **Sella**: The migration of the tunny studied by means of fish-hooks.

SYDNEY.

Royal Society of New South Wales, June 2.—M. S. **Benjamin**: A note on the rate of decomposition of commercial calcium cyanide. Decomposition was effected in a large closed glass container, and the percentage of hydrocyanic acid evolved was determined. The curves obtained indicate that carbon dioxide considerably accelerates the rate of change and factors other than the cyanogen content of the material affect the efficiency of a given dose of the material in practical fumigation.—G. **Harker** and R. K. **Newman**: Reactions depending upon the vapour at the interface of two immiscible liquids. The reaction between amyl acetate and acidulated water has been studied. The hydrolytic effect of liquid amyl acetate and of the mixed saturated vapour of amyl acetate and water at 100°, upon a surface of given area of dilute mineral acid, revealed a close agreement in the rate of hydrolysis. Taken in conjunction with the results previously obtained for benzyl chloride, it is therefore evident that at the interface of the two liquids the mixed saturated vapours of both liquids must be present. This is in agreement with the view of Van der Waals that there exists a continuous transition from the liquid to the vapour state at the boundary of any liquid.—A. R. **Penfold**: Notes on the essential oils from some cultivated Eucalypts. The specimens were grown from seed at Ashfield, near Sydney. The trees examined varied from three to eight years of age, and consisted of *E. Australiana*, *E. Macarthuri*, *E. citriodora* and *E. radiata* (*numerosa*). The *E. Australiana* was grown from seed collected at Wyndham, N.S.W., a place which yielded oils possessing a lævo-rotation of about -3.6 and containing phellandrene in small quantity, and as it would not meet the requirements of the various pharmacopœias the district had to be abandoned. The oils obtained from material grown

at Ashfield possessed an optical rotation of $+2\cdot5°$ to $3\cdot2°$ and were free from phellandrene. *E. Macarthuri* gave remarkable yields, varying from 0·5 to 0·74 per cent., as compared with 0·2 per cent. yield from the ordinary native material, whilst the geranyl acetate varied from 62 per cent. to 75 per cent., thus showing the influence of ecological conditions. *E. citriodora* yielded oils from 0·5 per cent. to 1 per cent., containing from 90 to 98 per cent. citronellal, and it would appear as if there were separate races existing within this species.—Miss P. **Nicol**: An investigation of the optical properties of selenium in the conducting form. Methods of preparing mirrors of selenium are described. The method gives values of γ_0 generally correct to within about 3 per cent. and of κ_0 to within 5 per cent. The values obtained vary within fairly wide limits, depending on the method of preparation (casting on glass, polishing, grinding, etc.). The results obtained are:

$\lambda =$ 6470-4170	$\nu_0 = 2\cdot7$ -$3\cdot36$	$\kappa_0 = 0\cdot45$-$0\cdot9$
$\lambda =$ 5890-5896	$\nu_0 = 2\cdot75$-$3\cdot06$	$\kappa_0 = 0\cdot77$-$1\cdot07$
$\lambda =$ 21900-8100	$\nu_0 = 2\cdot59$-$3\cdot02$	$\kappa_0 = 0\cdot90$-$1\cdot18$
$\lambda =$ 4400-4800	$\nu_0 = 2\cdot74$-$3\cdot04$	$\kappa_0 = 1\cdot05$-$1\cdot27$

Some rough measures in the near infra red indicated $\kappa_0 < 0\cdot1$ and ν_0 about 2·6. There was no definite indication of any relation between the temperature of transformation to the conducting form and the optical properties, nor was there any variation with the length of exposure to light or with the age of the specimen.

VIENNA.

Academy of Sciences, July 1.—F. **Hemmelmayr** and J. **Strehly**: Contributions to our knowledge of skoparin. Apparently this substance contains seven hydroxyl groups, and its formula is $C_{22}H_{22}O_{11}$ rather than $C_{20}H_{20}O_{10}$.—L. **Schmidt** and R. **Stöhr**: Two substances similar to stearine from *Asclepias syriaca*. A monovalent unsaturated alcohol $C_{31}H_{52}O$ and a divalent unsaturated alcohol $C_{45}H_{74}O_2$ have been obtained.—L. **Waldmann**: Petrographic description of the stones collected by L. Kober in the northern Hegas and in the Taurus.

INTERNATIONAL CONGRESS OF PHILOSOPHY (at Harvard University, Cambridge, Mass.).

SATURDAY, AUGUST 28, 1926.

CONTENTS.

African Natives and European Civilisation.

IN his presidential address to the British Association, H.R.H. the Prince of Wales spoke with singular felicity of the relations which do actually, and should, subsist between the State and scientific research. The discussion of a multiplicity of topics, which was released as it were from a floodgate immediately after the inaugural meeting, may have obscured the fact that the opportuneness of the Prince's reference to the application of scientific study to the problems of the Empire in our Dominions and Dependencies was conclusively demonstrated by the presidential address delivered in the Geographical Section on the following day. The lesson was further driven home by the discussion on the effect on the native races of Africa of contact with European civilisation which arose directly out of Mr. Ormsby-Gore's address, and took place in a joint session of the Sections of Geography and Anthropology.

His Royal Highness spoke as one who had had many opportunities in peace and in war to observe the facts, the necessities, and the possibilities of conditions in the Empire as a whole. In like manner, if in a more restricted field, Mr. Ormsby-Gore laid before his hearers the results of his journeys of observation in East and West Africa—journeys which may become as memorable and as far-reaching in effect as those of Joseph Chamberlain when the latter was Minister of State for the Colonies. Those who have followed the newspaper reports of Mr. Ormsby-Gore's travels with some knowledge of the problems which were then brought before him, will appreciate the acute observation and the balanced judgment which underlie his summary of the situation in regard to the economic development of tropical Africa and its effect on the native population. It is, however, of no little significance that his lucid summary of the needs of Africa and its people is followed by an acknowledgment of the greatness of our opportunities and our responsibilities and an appeal for the continued efforts not only of "officials and unofficials in Africa," but also of "the men of science over a whole range of human experience such as are meeting under the auspices of the British Association." It is pardonable if in these words we think we hear the statesman and the administrator rather than the president of Section E.

It cannot be denied that the need of constructive thinking for which Mr. Ormsby-Gore pleaded is urgent. The situation in Africa was summed up by one speaker in the discussion as one of depopulation and disintegration, and he went on to point out that the African native has passed in a brief space of time from the Stone Age to the present day. The final partition of Africa among

the European powers began in the last decade of the last century. Since then the economic development of the country has proceeded at a rapid pace, but especially in the last few years. Figures are quoted in Mr. Ormsby-Gore's address which are worth repeating. Between 1921 and 1925 the domestic exports of Nigeria increased from 8,250,000*l.* to 17,000,000*l.*; in the Gold Coast in the same period from 6,000,000*l.* to 10,000,000*l.* In East Africa the increase is even more marked, due almost entirely to the development of cotton-growing. In Kenya and Uganda the figures for the corresponding years show an increase from 2,250,000*l.* to 7,820,000*l.*, and in Tanganyika Territory from 1,100,000*l.* to 2,900,000*l.* This sudden accession of wealth would not be without its element of danger in any community; but when it is realised that the greater part represents the earnings either as producers or as wage-labourers of a population to whom 'money' is still novel, and whose ideas of a currency and medium of exchange not so long ago were limited mainly to 'brass rods' or 'cloth,' it must be apparent that the problem is both immediate and grave. It is a problem which demands statesmanship, and a statesmanship which is informed with an intimate knowledge of the African, of his institutions, and of his needs.

It is not possible to set back the clock. For good or for ill, the economic development of Africa is bound to go on under pressure of an increasing world-demand for its raw materials and its market for imports. Apart from certain restricted areas which will be exploited for their mineral wealth, it will be developed as an agricultural country. In tropical Africa, where white labour is impossible, that development will depend upon the native. Even in South Africa it is doubtful if white labour will ever be able to hold its own. Whatever may be the ultimate result in South Africa, in the tropics it seems clear, owing to climatic conditions and the question of prestige, that the function of the white man is to act as an administrator or employer and the guide and teacher of the native.

Up to the present it cannot be said that this rapid development of Africa has been for the good of the native on the whole, even though it be recognised that certain benefits have accrued to him. It is doubtful, indeed, how far these benefits may be for his ultimate good unless steps are taken to neutralise the inevitable disabilities by which they are accompanied. It has also to be admitted, as has been pointed out recently by a resident of many years in the remoter parts of East Africa, that the native does not always accept the advent of the white man who comes to exploit his land as an unmixed blessing. The African has a distinctive culture of his own, in which the cardinal features are the religious beliefs which are interwoven as an essential element in every aspect of his life, and the communal spirit which informs his thoughts and actions as a member of a tribal group. Notwithstanding differences as between tribes and peoples in the form of their political organisation, this is true of all in general terms. Especially is it essential to remember that the ultimate sanction of chiefly and tribal authority is religious. Further, apart from provision for the needs of the family and any contribution due to the chief or the community, the idea of the economic value of labour applied to production from the land or of wage-earning is alien to the native mind. Until recently, and as is still the case in many tribes, wealth consisted exclusively of wives and cattle. One of the reasons for the imposition of a hut-tax on the native population in South Africa was the hope that incidentally it would familiarise the native with the advantages of wage-earning and thus increase the supply of labour.

It is self-evident that the sudden impinging of European civilisation on a culture of this type, and the rapid economic development of the country, are bound to result in an equally rapid disintegration of native institutions. The growth of a class of native producers and of wage-earners has rendered the individual conscious of his individuality as a unit rather than merely as a member of a social organism, while introduction to the tenets of Christianity, an individualistic body of belief, has still further strengthened this tendency. The authority of the chief and the sense of responsibility to the tribe have been undermined, and the religious bond upon which they depend has been loosed. In the coast towns of West Africa, natives have become completely detribalised, and if the process is allowed to go on unchecked the existing tribes are in danger of becoming undisciplined mobs. Again, the native system of land-tenure, about which, incidentally, insufficient is known, is in danger. The economic value of land is beginning to be appreciated by the native, and where land is vested in the chief, this has introduced an entirely new relation of landlord and tenant as between the chief and the individual member of the tribe. Of the importance of a knowledge of the system of land-tenure, the disastrous experience of South Africa up to the passing of the Glen-Gray Act is a sufficient indication. Here, too, notwithstanding the reservation system, detribalisation, except in the case of the Zulu, is proceeding rapidly.

Of the results of this tendency to detribalisation, little need be said. They are obvious. The lack of restraint, and the accompanying break-up of the *morale* of the native, unless checked, are bound in the long run to be disastrous. They must accelerate the depopulation of the country, which, owing to disease and especially infant mortality, is already a serious factor in the

situation. Improved sanitation, a higher standard of nutrition, and increased efficiency in medical service may, however, be expected to cope with disease as time goes on; but an informed and intelligent guidance based upon a sympathetic understanding of native psychology, which will control and direct into safe channels the inevitable modification of the full tribal system, is an essential condition of the well-being of the native, and in the long run of the prosperity of Africa.

The present tendency to unchecked detribalisation is the more to be regretted in that the African native is one of the most adaptable of all the primitive races in the world, when the innate conservatism based on his religious taboos is not affected. This is shown by the readiness with which the native has mastered new arts of life in the course of the opening up of his country. Many of the African natives have beside, as the study of their history and institutions shows, a remarkable instinct for social and political organisation. The genius of Chaka, the great chieftain of the Zulu, is by no means unique in the annals of African tribes. This capacity for organisation and government is not confined to the men but has been displayed on more than one occasion by women, who by some accident or other have attained positions of authority.

A hopeful feature of the situation is the intense desire of the African for education. Hitherto the only form of education available for the native, with the exception of the interesting experiment at Achimotu, has been upon European lines; but education in Africa must take a new orientation. It is clearly of little use to offer the African a system of education which was designed originally to meet the needs of a European environment. Too often it has been the case that the curriculum of native schools has been framed with an eye only to the literary side of education, to the neglect of practical subjects. Yet it is not enough to insist on the need for vocational training. Even while recognising the excellence of much of the work which has been done in this direction, too great emphasis cannot be laid upon the fact that the education of the native must be based upon an intensive study of the culture, the institutions, and the needs of the African population. Much, it is hoped, may yet be effected through the Committee on Education of the Colonial Office. For many years the anthropologists have been collecting the facts, and although they are well aware that these facts may still be incomplete in certain respects, yet in response to Mr. Ormsby-Gore's appeal for the assistance of scientific workers they are ready and willing to place their knowledge at the disposal of the administrator for its practical application in the training and government of the native community of the new Africa.

An Indian Clan in Wales.

The Dialect of the Gypsies of Wales: being the Older Form of British Romani preserved in the Speech of the Clan of Abram Wood. By Dr. John Sampson. Pp. xxiii+230+419. (Oxford: Clarendon Press; London: Oxford University Press, 1926.) 84s. net.

THE majority of people are surprised when they are told that in almost every country of Europe, and even in America, there is spoken to-day a language which was brought out of India by a tribe or tribes between twelve and fifteen hundred years ago. This is the language of the people known to us as Gypsies, to themselves as Rom or the like, a word which phonologically is the exact equivalent of the modern Indian Ḍom, a general name for an outcast, so-called criminal tribe, who in many places act as scavengers and burners of corpses, and in all places are ready to augment their earnings by stealing or other anti-social practices. The Gypsies of Palestine and Syria still call themselves Dom, just as with them a spoon, *roi* in European gypsy, is *dowi* (and in modern Hindi *ḍoī*).

It has long been recognised that the speech of the Gypsies, which, as regards the European branch at least, differs comparatively little from country to country, is like the modern Indo-Aryan vernaculars of India—Kashmiri, Panjabi, Sindhi, Gujarati, Marathi, Hindi, Bengali, and the rest—descended from an old language of which we have the literary form in the language of the Rigveda and in Sanskrit. Consideration of its sound-changes and of its vocabulary makes it certain that the Gypsy language, or Romani, originally belonged to the same dialect-group as gave birth to the present central languages of India, such as Hindi. At a comparatively early period, however, which must be dated before the beginning of this era, they had wandered away to live for a time with the ancestors of the wild and little-known tribes of the north-west frontier, among the mountains of the Hindu Kush. Linguistically these tribes are very conservative in certain respects; and, being with them, the Gypsies preserved certain sounds and groups of sounds which were afterwards lost by those they had left behind in India proper. Whereas, for example, in India an original *t* or *d* coming between vowels was altogether lost, it is preserved in some form or other only by two of these north-western dialects and by Gypsy. European Gypsy keeps them under the form of *l*, Syrian Gypsy under the form of *r*. It is then of peculiar interest to note that, of the two north-western dialects which also preserve them, Khowar, spoken in Chitral, has *r*, and Kalasha, spoken farther south, has *l*. Thus the word which in Pali (a later form of Sanskrit) is *deti*, 'he gives,' is Hindi *de*, but Khowar

dōr, Kalasha *dali*, Syrian Gypsy *der*, European Gypsy *del*.

About A.D. 400 this region was disturbed by the Hun invasions of India. By them perhaps the Gypsies were set in motion towards the west. At all events, before A.D. 900 we find them in Persia, where various legends are related to account for their presence. A succinct account of their wanderings from here has been given by Dr. Sampson in a recent number of the *Journal of the Gypsy Lore Society*. Their path can be traced by the words which they picked up and adopted from the languages of the countries through which they passed. From Persia the Gypsies who changed original *-t-* to *r* migrated into Syria, from where some went north into Transcaucasia, others south into Egypt. Those, on the other hand, who changed *-t-* to *l* passed on into Armenia, where some remain until the present day; others, driven forward by the Turk inroads, migrated through Asia Minor into the Balkan Peninsula before the end of the eleventh century; and here it is that we first have definite historical record of this strange people. In Greece they stayed for a long period, to which also the numerous Greek loan-words in their language bear witness. But early in the fifteenth century—again before the threat of the Turkish invasion—they once more began their wandering. Their bands moved rapidly, and in a very short while they had appeared in almost every European country.

Wherever they went they were persecuted, and statutes were passed for their suppression and expulsion. It is therefore easily to be understood that it was greatly to their advantage to have a language which was not intelligible to their enemies. This doubtless was a powerful factor in the preserving of their old Indian tongue, despite the comparative smallness of their numbers and their wide separation both from the land of their origin and among themselves. Of recent times, however, and particularly in England, where they have never been very numerous, their speech has degenerated into a jargon, which is little more than a certain number of Gypsy words set in an English framework, with English grammar and English syntax. We may note, in passing, that the borrowing has not been entirely one-sided, and the number of slang words and phrases taken from Gypsy is probably considerable. One at least has acquired universal use: for the word 'pal' is English Gypsy *phal* (in which *ph* is an aspirated *p*, not *f*), meaning 'brother,' Continental Gypsy *phral*, and direct descendant of Sanskrit *bhrātā*.

Those readers (and fortunately they are many) whom the works of Borrow have acquainted with the Gypsies and their language, though already in a much degenerated form, will be astonished when they study the monumental work now before us on the language spoken by a Gypsy clan in Wales to-day. This is still really an Indian language, not a mere jargon. Students, not only of language and of the Indian languages in particular, but also of culture and folklore, owe a great debt to Dr. Sampson, both for his original discovery of Edward Wood, the Welsh Gypsy harper, at Bala in 1894, and for the enthusiasm and perseverance which has carried him through thirty-two years of patient collecting and sifting and arranging of stories and other linguistic material from this little Indian clan among the mountains of Wales, work which has at last resulted in a volume of more than 650 pages. It is by far the most complete and most accurate description of any Gypsy dialect that we possess. The first 230 pages are devoted to a description of the sounds, forms, and syntax of the language; the next 419 to a vocabulary, full of quotations, and precisely indicating the meaning and use of each word. If there is one part more than another to which we would refer as especially valuable, it is the pages which contain a minute and scientific description of the sounds of the language. We regret that it was impossible to include a certain number of texts, but presumably the already great size of the volume forbade a further addition. But those who are interested will find a large number of stories published by Dr. Sampson, with notes and translations, in the *Journal of the Gypsy Lore Society*.

In one respect only do we criticise Dr. Sampson's work adversely. Comparative philology, though almost the first impulse to its scientific study was given by that great English scholar and orientalist, Sir William Jones, has never been a plant of vigorous growth in England; and the languages of India, which Englishmen have had peculiar opportunity of acquiring, have suffered more at the hands of amateur philologists perhaps than any other group of languages. The scientific study of the history of the modern Indian languages is a comparatively recent growth, and the workers are still far too few. Gypsy, like the other Indian languages, has also suffered at the hands of amateurs. Some of its students have been famous linguists; but the greatest of them all, Miklosich, wrote before the fruitful ideas of the "Junggrammatiker" saw the light and changed the whole basis of the science of comparative philology. Dr. Sampson unfortunately yielded to the temptation to combine history with description; and throughout the book he attempts to trace the history of Gypsy from Sanskrit onwards. But though the science of language has made such enormous strides during the last fifty years, Dr. Sampson does not seem to have progressed beyond

the days of Miklosich. Examples of this are to be found in profusion on almost every page. We will take two only, to serve as illustrations of our criticism.

Without a recognition of the principle of the constancy of so-called sound-laws, there can be no science of etymology. This principle is that a given sound in a given dialect will develop in the same way in all words in which it appears under the same conditions. Thus Sanskrit words containing intervocalic *-t-*, if they survive, will in Hindi lose the *-t-* altogether, in European Gypsy show it as *l*. An etymology which neglects this rule is at once suspect; and if it is to be upheld, some special reason must be sought, such as borrowing from another dialect or the like. But Dr. Sampson has no compunction in making etymologies which go contrary to well-established rules of Gypsy, and that without noting the fact or seeking for explanation. Thus it is a sound-law of Gypsy (and of nearly every other modern Indo-Aryan language) that original intervocalic *-k-* is lost: this is admitted by Dr. Sampson, who gives for example the Sanskrit ending *-ako*, which became Middle Indian *-ao* and Gypsy *-o*, or the Sanskrit *yūkā*, 'louse,' which became Gypsy *juv*. Yet without hesitation he derives Gypsy *šukār*, 'quiet,' from Sanskrit *sukṛta-*, 'well done' (which in Gypsy would have become something like **suil*). It is, on the contrary, doubtless from Sanskrit *śukrá-*, 'bright, pure, clear.'

Secondly, Dr. Sampson compares Gypsy words not only with what he considers the Sanskrit originals, but also with their Hindi congeners. Now, just as French contains not only inherited Latin words (like *père*, derived from *patrem*), but also borrowed Latin words (like *paternité*, borrowed from *paternitas*), so too Hindi has both inherited Sanskrit words and borrowed Sanskrit words. If we wish to investigate the history of Latin sounds, say in Italian and French, we must compare the inherited Latin words in one language with the inherited Latin words in the other language, not an inherited word in one with a borrowed word in the other: we must compare Italian *padre* with French *père*, not with *paternité*. But Dr. Sampson, in countless cases, compares an inherited Gypsy word with a borrowed Hindi word: for example, he compares Gypsy *thulo*, 'fat' (connected with Sanskrit *sthūlá-*, 'strong'), not with, say, the inherited Nepali word *ṭhulo*, id., but with the borrowed (and only very literary) Hindi word *sthūl*.

Such an attitude and such mistakes invalidate the whole of Dr. Sampson's comparative work: it cannot be accepted as in any way a trustworthy guide. It is indeed a pity that this fine book, which is otherwise such a splendid monument to the author's scholarship, should be so marred. How far better would it have been if either he had followed his first intention (as expressed in the preface) and left the historical side alone, or by a much profounder study of comparative philology in general and Indo-Aryan philology in particular have fitted himself for the task of comparison with other Indo-Aryan languages. But since perfection is not attainable by man, we may be grateful that Dr. Sampson has given us a work which not many could have accomplished.

R. L. TURNER.

Ice Ages.

Ice Ages: Recent and Ancient. By Prof. A. P. Coleman. Pp. xliii + 296. (London: Macmillan and Co., Ltd., 1926.) 17s. net.

EARLY glaciologists wrote of 'The Ice Age,' next of 'The Great Ice Age,' and when it became obvious that there had been earlier refrigerations not inferior in intensity to the latest, of 'The Quaternary Ice Age'; now we have a glacial history of the earth, and from the hand of a master of the subject. Many of the glacial deposits described have only been discovered within the past few years; it is probable that many more will be found in the future, but Prof. Coleman presents enough material to enable us to form an idea of the distribution of glaciation both in space and time.

Deposits referable to ice are now known or suspected from nearly all the main geological formations, but many of them are of small extent and can be attributed to valley or at most piedmont glaciers. Major glaciations are known from the Lower Proterozoic or Huronian, the Upper Proterozoic to Lower Cambrian, the 'Permo-Carboniferous' and the Pleistocene. Minor glaciations are known or suspected at other levels in the pre-Cambrian (though owing to the difficulties of correlation it is not possible to say how many), in the Ordovician (North America and doubtfully in Europe), and in the Silurian-Devonian (Alaska, eastern Canada, Cape Town). The great 'Permo-Carboniferous' glaciation was manifested in five continents at least, but mainly in the southern hemisphere and in India; in strong contrast was the generally warm Mesozoic, from which only two glacial deposits are described, a tillite from central Africa west of Lake Tanganyika, probably Triassic but possibly older, and a Jurassic moraine from California, both probably formed by piedmont glaciers.

During the whole of the Mesozoic the sea-level temperature remained high, and the great cold-blooded reptiles were able to multiply and dominate the earth. Coleman attributes their sudden disappearance to a "slight dip in temperature at the end of the Cretaceous, too small to be called an ice-age." This slight cooling is indicated by the valley moraines of Cape Hamilton

in the Antarctic and the Cordilleran region of North America; the ice-transported boulders of the Cretaceous of South Australia and England are not mentioned, presumably because they are attributed to shore ice and not to land ice. There may have been mountain glaciers in the Miocene of Iceland and Europe, but these were local, and the next great cooling occurred at the close of the Pliocene and still continues.

These phenomena offer a definite meteorological problem, which the author sets out clearly in words which are worth quoting:

"Under normal conditions the world has a relatively mild and equable climate with no permanent ice at low levels even in the polar regions."

"From time to time . . . there have been relatively short periods of cold accompanied by a great extension of mountain glaciers, and sometimes also by the formation of ice-sheets at low levels. In the most severe visitation of the kind ice-sheets invaded the tropics on three or perhaps four continents."

"Ice ages are, in most cases, broken by interglacial periods of milder climate. Sometimes this occurs two or three or more times, indicating a comparatively rapid oscillation from cold to warm and warm to cold."

"All parts of the world have their temperature lowered during an ice age, the tropics as well as the temperate and arctic zones."

The author then turns to the consideration of causes, but gives only a rather mechanical discussion of the various theories of climatic change which have been put forward from time to time. Wegener's theory of continental drift is mentioned, but without enthusiasm. Elevation perhaps comes nearest to a solution, but fails to account for world-wide cooling. The conclusion is that no single cause suffices; "some combination of astronomic, geologic, and atmospheric conditions seems to be necessary to produce such catastrophic events in the world's history."

The difficulty of the problem is increased by the apparently haphazard way in which glaciations have developed. Time and again the author comments on the paradox of field-work, especially on Permo-Carboniferous tillites, beneath an almost vertical sun in a temperature suggestive of anything but ice. On the other hand, so far as is known at present, the Antarctic continent escaped glaciation until the close of the Mesozoic, though of course the great Antarctic ice-sheet may hide traces of many older glaciers. The north-east of North America, where the Quaternary ice-sheets reached lower latitudes than anywhere else, has suffered glaciation over and over again. In the Upper Carboniferous this region bore glaciers which indeed pale into insignificance beside the contemporaneous ice-sheets of the south, but would be sufficiently remarkable in any other period. The same region was ice-covered in the Devonian, the Ordovician, at the close of the Proterozoic, in the Lower Huronian (a photograph shows the remarkable feature of a Huronian tillite smoothed and striated by a Pleistocene ice-sheet), and perhaps at two horizons in the Archæan —seven or eight glaciations in the same or neighbouring areas. Other regions which have suffered repeated glaciation are Alaska, South Africa, and south-east Australia, though South Africa was not glaciated during the Pleistocene.

It almost seems as if, given certain conditions, and especially a world-wide cooling, glaciers and even ice-sheets can develop in any latitude, but have a preference for certain localities. From this point of view it may be only an accident that the two great ice-sheets of the present day occur in high latitudes. Their formation is not entirely a matter of temperature, since we are faced by the idea that during most of geological time the polar regions were free of land ice even while lower latitudes were being glaciated. Apart from pole-wandering, the only theory which throws any light on this anomaly is Paschinger's, not mentioned by Coleman, that glaciation depends on the relation between the zone of maximum snowfall and the snow-line. It may be profitable to try to fit this theory to the facts before us.

As we go from the lowlands up the slopes of a mountain range, we find that the snowfall increases up to a certain level, above which it again decreases; this level depends mainly on the humidity and the temperature during the wettest season. Quite distinct, depending mainly on the summer temperature, is the snow-line. If the snow-line is above the zone of maximum snowfall, the glaciers will be small; if the snow-line is the lower, the glaciers will be large, and with sufficient snowfall may descend to low levels. In the moist equatorial regions the two zones are close together, and a small depression of the snow-line would produce a considerable extension of the glaciers.

It seems probable that glaciers or ice-sheets must always *originate* on high ground, but for a glacier to develop into an ice-sheet a large area of more or less level ground is required at a temperature low enough for the ice to spread out as a piedmont glacier. In high latitudes this land may be low, but in low latitudes it must be initially at a high level. Once the ice-sheet has reached a certain size, however, it imports its own climate, and the initially high plateau may be depressed nearly to sea-level without necessarily destroying the ice-sheet. There are several reasons for this; one of the most important is that a snow surface reflects four-fifths of the solar radiation falling on it, and another is that a large ice-sheet is naturally occupied by an anticyclone with outwardly directed winds. The relations between snow-line and zone of maximum

snowfall probably depend on conditions of storminess and vertical temperature gradient which are due to general causes; when these are favourable, glaciers will form which may develop into ice-sheets in suitable localities, determined partly by configuration, which is independent of latitude, and partly by location relative to storm tracks and oceans. The latter proviso causes the repetition of glaciation in certain localities which are not necessarily the coldest parts of the globe. During the course of an ice-age the most suitable location may change, which brings us back to Coleman's speculation that the Greenland ice-sheet may represent the continuation of the eastward trend of glaciation in America, having commenced later than the American ice-sheets and persisting after them.

The author has done good service by uniting in one volume a large mass of material which was formerly only available in scattered papers or, in the case of his own observations, had not previously been published. The volume maintains the high standard which we expect of the publishers; it is lavishly illustrated by photographs of great interest, and the only error which the reviewer has noticed is the name "Grygalski" on page 286.

C. E. P. BROOKS.

The Sylvester Programme in Algebra.

Matrices and Determinoids. By Prof. W. E. Cullis. (University of Calcutta: Readership Lectures.) Vol. 3, Part 1. Pp. xix + 681. (Cambridge: At the University Press, 1925.) 63s. net.

WE are all familiar with Cartesian co-ordinates denoted by $[x, y]$, where two numbers written in an assigned order specify the position of a point in a plane. Unless $x=y$, the symbol $[y, x]$ denotes quite a different point. This simple geometrical illustration is enough to shew that in pure algebra, quite apart from geometry, a pair of numbers (or indeed a whole row of n numbers) in an assigned order might be considered as a single entity A. Such an A is sometimes called a vector (if $n>1$), but it is a special case of a matrix of rank one.

Yet, curiously enough, the more natural set of numbers to consider as a compound unit in algebra is not a row so much as a *square* arrangement of numbers. Nine numbers put in square formation, three by three, are what Cayley called a matrix of order three. Cayley first saw the value of treating it as a single magnitude. The reason is this: that matrices may be added, subtracted, or multiplied together and the result is always a matrix. This is not entirely true of vectors.

As a square is a special case of a rectangle, one may substitute for the idea of a square matrix that of a rectangular matrix of mn numbers, arranged in m rows and n columns. The author has taken this as his leading idea throughout the series of volumes, the third of which we have now reached. But the arrays

$$A = \begin{matrix} 1, 2, 3 \\ 4, 5, 6 \end{matrix} \qquad B = \begin{bmatrix} 1, 2, 3 \\ 4, 5, 6 \\ 0, 0, 0 \end{bmatrix},$$

show that the oblong case is really included in Cayley's square, since the actual properties of matrix A and matrix B are effectively the same.

The B matrix here may be extended to the fourth or higher order simply by fixing columns and rows of zeros to the right and below the existing square. All such matrices share with A the same rank: it is the *rank* of a matrix which is its most important feature. The rank of A or B here is two, and in general cannot exceed the smaller of m and n.

The work of which the bare elements have just been explained is founded on original ideas of three of our countrymen—Cayley, Sylvester, and H. J. S. Smith—and it dates from about seventy years ago. As so often happens in mathematics, work started in England has been brought to fruition abroad. So the work of Cayley was advanced almost out of recognition by Frobenius, and that of Smith by Weierstrass. Sylvester, who foresaw an important future for matrices, outlined a programme which has been systematically adopted by Prof. W. E. Cullis, who has done a real service to the mathematical world by carrying it out in all its breadth and detail.

The present book runs to seven hundred pages, yet it is only part of volume three. It is conceived in a spacious, leisurely spirit. There is something portentous in the massiveness of the structure. The author believes in his thesis, but is in no hurry to convince the sceptic or the ignorant. He promises in volume four a wealth of practical applications to analytical solid geometry, the theory of groups, dynamics, and the like, which will justify the patient elaboration of the preceding algebra. Everything is thoroughgoing and sound, and in fact volume three covers a larger field than its title implies. It is the only really complete account, in the English language, of many fundamental facts of algebra bearing on polynomials, factors, eliminants, and so on.

The book deals with three great branches of the matrix theory, as grouped round the conceptions of (1) *potent divisors*, usually called invariant factors (*elementarteiler*), (2) *commutants*, and (3) *invariant transformands*. The first of these is the difficult general theory governing the classification of algebraic systems illustrated at their simplest by the conic or the quadric surface, or a dynamical system of small oscillations. The second and third of these are bound up in the study

of the respective equations

$$AX = XB,$$
$$AXB = X,$$

where A, B, X are matrices and X is the unknown quantity. Bearing in mind that ordinary algebra is the study of the simplest possible matrix, where $m=n=1$, we have a clue to the interesting general case. Non-zero solutions exist provided A and B satisfy a specific condition analogous to $A=B$ and $AB=1$ respectively, for this simple case.

Incidentally, a problem of Frobenius, to find the square root of a given matrix, is fully discussed.

The treatment of the work brings out forcibly the propriety of thinking of variables X and constants A in a relation

$$f(X, A, A', \ldots) = 0,$$

where $X, A, \ldots$ are matrices. The reader is brought to see how far-reaching are the ordinary conceptions of elementary algebra, such as the notion of solving an equation.

The book is not easy reading, in spite of the exceeding care taken to explain or prove everything. The reason is that the formal general case precedes special instances. Algebra is peculiarly adapted to the converse use: a chess board of nine or sixteen squares suggests most of the properties of a chess board of n^2 squares. Also several crucial results are disguised in small print.

The book has been carefully printed and contains few mistakes: one is only sorry that the Cambridge Press is unable apparently to do it full justice by returning to the use of the quality of paper or ink, or both, which go to make the first volume.

It may be added that the second name in the title is relatively unimportant in this volume. A determinoid bears to the rectangular matrix the relation which a determinant bears to the square matrix.

We are under a real debt to the distinguished author for this latest instalment of a mature and suggestive work, and we look forward to the promised further developments with interest.

Our Bookshelf.

Problems of Philosophy: an Introductory Survey. By Prof. G. Watts Cunningham. (Modern Thinkers' Library.) Pp. xxi+453. (London, Calcutta and Sydney: George G. Harrap and Co., Ltd., 1925.) 8*s*. 6*d*. net.

THIS is a useful book, with a modestly misleading title. When a writer introduces 'problems of' or 'studies in' this or that subject, he is commonly taken to offer his own particular theories on a limited group of more or less connected topics. Prof. Watts Cunningham has a less personal and more generous and catholic intention. He writes, broadly speaking, about all the problems that there are, and with the utmost objectivity and detachment. What he gives us is, in effect, a guidebook to contemporary metaphysics, as clear and simple as it can well be made, and so skilfully compacted that the intelligent use of a table of contents and an index will conduct an inquirer's finger straight to the sections relating to any one of the major issues of current interest, and let him find there just how the controversy stands, and why it is where it is. That is no small performance—it has meant selecting and correlating the significant 'tendencies' of endless recent discussion, indicating the historical background of each question, and making plain the cruces of each decision.

The plan of the book is simple. Part 1 defines, partly by contrast, the scope of philosophy and the nature of its distinctive method. Part 2 examines some central problems in the theory of knowledge. Parts 3, 4, and 5 trace the evolution from matter to mind, taking the widest possible survey of what is involved in these terms. Part 6 discusses the nature and status of our experiences of 'value.' This bare indication of contents is perhaps all that need be given; for, all through, the writer is little concerned to recommend a theory, but rather to expose the issues, to show what considerations are relevant and what are the implications. Plainly enough, Prof. Watts Cunningham's own sympathies are with the idealist tradition; but his survey is thoroughly impartial in spirit and in execution. Nowhere, in the nature of the case, does it cut very deeply; but it very well points the ways.

H. J. W. H.

The Physical Chemistry of Steel-making Processes: a General Discussion held by the Faraday Society and the Iron and Steel Institute, June 1925. Pp. 167-296. (London: The Faraday Society, 1926.) 8*s*. 6*d*. net.

As Dr. W. H. Hatfield has said in the discussion before us, "there is to be found in this collection of papers by far the most weighty and valuable treatment of the subject of furnace reactions that we have had." Almost every phase of modern steel-making is dealt with, and, although the symposium reveals, as the chairman, Sir Robert Hadfield, pointed out, the many important gaps in our knowledge of the reactions which take place at these high temperatures and of the physical data necessary for their elucidation, the general feeling after reading the present volume will be that a distinct advance is being made in this important scientific and industrial subject.

The paper by McCance on "Balanced Reactions in Steel Manufacture," a continuation of earlier work by the same investigator, represents probably the most important single contribution yet made to the subject. Experimental confirmation on an industrial scale is necessarily a slow process, and there are clearly many points on which such proof is required, but the excellent manner in which all the threads hold together and the agreement with experimental fact, so far as has yet been found, offer good reason to believe that in time the confirmation will be obtained. "A Study of the Reactions of the Basic Open-Hearth Furnace," by Mr. T. P. Colclough, is another outstanding contribution. His contention that the influence of temperature is definitely subordinate to that of slag composition is of fundamental importance. Among the other papers,

that on the reactions in the electric furnace, by Mr. F. T. Sisco, and another dealing with the general physico-chemical aspect of steel-making, by Mr. A. L. Feild, are well deserving of mention. To all those interested in any degree in the chemistry of the manufacture of steel, the volume is of the utmost importance and will be read with the greatest interest. F. C. T.

Science: an Introductory Textbook. By E. J. Holmyard. Pp. x+230. (London and Toronto: J. M. Dent and Sons, Ltd., 1926.) 4*s*.

MR. HOLMYARD is well known as one of the most active and vigorous exponents of the humanistic school of science teaching, and his viewpoint finds complete expression in this very entertaining and instructive volume. We could wish for nothing better than that the scoffer at the 'romance of science' should read it. For our part we found ourselves compelled to complete a first reading in one sitting. Mr. Holmyard's style is peculiarly happy and easy, and one feels that he thoroughly enjoyed his task. His object is to present science as a whole to the young beginner. He refuses to admit of barriers as between one branch of the subject and another, and in this he is right. Further, he has shown how it can be done. He enlists to his purpose the framework of the past—the Aristotelian scheme of the four 'elements' of air, water, earth, and fire, and after a historical introduction he deals with these one by one, and makes each the theme for a series of facts and phenomena of Nature. So we find simply and naturally interlocked a number of important and fundamental principles usually detached into separate 'subject' volumes. Finally, passing from the inanimate to the animate, the author presents a brief but interesting account of the phenomenon of life.

Naturally there is a serious danger of 'overdoing it,' but Mr. Holmyard has wisely preferred the errors of omission to those of commission. At the same time, we feel that the book would have been greatly strengthened by some short account of the astronomical scheme of the universe. In our view a general survey of science, even for the young beginner, definitely requires this, and its place is as pertinently at the beginning as is the study of life at the end.

The production by the publishers is, with the exception of some rather crude 'portraits,' very well done, and we have nothing but praise for a book that will commend itself to all interested in the teaching of science. I. B. H.

Life of Plants. By Sir Frederick Keeble. (Clarendon Science Series.) Pp. xii+256. (Oxford: Clarendon Press, 1926.) 5*s*. net.

AN initial embarrassment that confronts one who would become acquainted with the present achievements and aims of botanical science is the large number of books dealing with plants from which a choice may be made. The subject has been approached from so many points of view that curiosity is aroused as to wherein any new volume can differ from its predecessors.

Those who are conversant with the writings of Sir Frederick Keeble—who have read his fascinating "Plant Animals," for example—will not be surprised to find that the present book *is* different from those we already know. Excellent as many of the latter are in providing detailed and accurate information about plants, carefully and clearly though some of them are written, we have met with no book which succeeds in conveying to the same degree as does the present small volume the all-pervading importance of plants in the scheme of living things, or the wonder and romance of their activities.

The information is there also—the amount that has been packed into 250 pages is indeed astonishing—but the reader is given the impression of being led into a new country by roads which permit of ever more and more extensive views, the facts and arguments which border the road and define its direction never being allowed to grow into a hedge tall or dense enough to oppress the traveller or to obscure the surrounding prospect. Therein, perhaps, lies the one danger. The reader may be so enthralled by the scenery around him that he may be tempted to give insufficient attention to the details of the foreground. This omission can be made good, however, when the journey is repeated, as no doubt it will be more than once.

Few are the books which can justly claim to have completely fulfilled their author's hopes: fewer still those in which this or that modification would not seem an improvement to some reader. No doubt some will say that a rather disproportionate amount of space is given to Mendelism, or that the contrast between sporophyte and gametophyte phases, with the dominance of the latter in some groups of plants, has been insufficiently emphasised. Exception may also be taken by some to the wholehearted acceptance of hormones to explain the sensitive reactions of plants. Such, however, are but minor matters and do not affect the picture as a whole, which is surprisingly complete in view of the size of the canvass.

In the preface, the author pleads that we should judge leniently his failure to accomplish the task he set himself. If he has not succeeded in satisfying himself, he has earned the gratitude of his readers by giving them a delightful and stimulating book.

Comparative Philosophy. By Paul Masson-Oursel. (International Library of Psychology, Philosophy and Scientific Method.) Pp. vi+212. (London: Kegan Paul and Co. Ltd.; New York: Harcourt, Brace and Co. Inc., 1926.) 10*s*. 6*d*. net.

"COMPARATIVE PHILOSOPHY," by M. Masson-Oursel, gives the impression of a compilation. There is an introduction by Dr. Crookshank, a notice that Part II. has been translated by V. C. C. Collum, and a dedication to M. Lévy-Bruhl, whether by author or translator or editor does not appear. The book itself deals largely in generalities and is interspersed by a long table of comparative chronology and various bibliographies. There is nothing peculiarly original or even striking in the actual matter of the book, and now and then we come on fairly long quotations from the Greek which are left untranslated, although the book is scarcely designed to appeal only to scholars.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Classification of Research Work.

IT has often been found difficult to discriminate between the different classes of work carried on by research laboratories. This difficulty is intensified when, for such purpose as the founding of an industrial research association, it becomes necessary to explain these differences before persons to whom such work had previously been an unknown quantity. In these circumstances the lack of an exact terminology can cause much confusion; three members of a committee can use the expressions 'fundamental,' 'pure,' and 'applied' research, when all three may nevertheless wish to imply the same thing. Such explanatory terms as 'deep-digging' and 'trouble-curing' are less unmistakeable, but they fail to convey shades of meaning.

One grouping which served a useful purpose was made by separating investigation from research proper. This gave the successive steps of pure research, fundamental research, applied research, investigation, invention, and routine. Here a distinction was intended to be drawn in the second instance between the pure research of a university laboratory, and research which is just as free to pursue its studies to any depth or intensity, without regard to their ostensible usefulness, provided only that they are restricted to material offered by the industry concerned. However, the nomenclature employed was confusing, but the writer eventually realised, while assisting to explain these meanings, that the conception of 'restriction' could be used to provide a very tolerable classification which was implicit in the whole discussion of the topic. Such a classification is almost obvious when research work is looked at from the organiser's view of an industrial research department, with its conjoint laboratories, workshops, and manufacturer's plant.

This classification may be illustrated by the mechanical analogy of degrees of freedom, such as those of a three-point support. The three essentials of any research for our present purpose are the Method, the Subject, and the Aim. Accordingly, as the research worker is left free to pursue his own course in each of these respects, or in so far as he is restricted to a limited choice of their possibilities, so we obtain eight separate classes of research activities, covering a very wide range.

The fundamental relation of the experimental method to the advancement of natural knowledge, observed by Francis Bacon, evidently sets the Method in a position of superiority over the other two. Consequently, such work as is done with its methods under restriction is, speaking scientifically, of a low order; such is the plain routine of works-control laboratories, or of a testing-room. On the other hand, the university laboratory is potentially unrestricted—finance excepted—not only in its methods, but also in the subjects studied, and in its aims; it is free in all three degrees, to use mathematics or glass-blowing, to study nebulæ or tadpoles, and to take its aim no closer than at the advancement of human knowledge. The testing-room is not only restricted to quick routine methods in making its tests, as also in the study of its statistical data, but its subject matter is restricted to such material as is manufactured or used in its own factory, and its aim is equally restricted to narrow and well-defined ends. Between these two lie six other possible classes, and it is interesting to see that they do actually correspond to most of the recognisable classes of research work. We will briefly examine them in regular order, though the reader will best draw his own examples out of his own experience.

(*a*) FREEDOM IN METHOD, AIM, AND SUBJECT.—As already noted, this class is indubitably pure research, typified by that of the university.

(*b*) FREEDOM IN METHOD AND AIM, BUT RESTRICTION IN SUBJECT.—This is what the most enlightened industrialists imply by the term 'fundamental research.' It consists in purely scientific study of such material as possesses industrial importance, and is undertaken to broaden the basis of knowledge upon which effort ultimately rests. A determination of the chromosome numbers in species of Gossypium for the cotton industry will serve as an example.

(*c*) FREEDOM IN METHOD AND SUBJECT, WITH A RESTRICTED AIM.—For this class we might cite most of the work done on behalf of public health, which has one definite aim, though it studies mosquitoes or abattoirs, and uses statistics or string galvanometers.

(*d*) FREEDOM IN METHOD ONLY; AIM AND SUBJECT RESTRICTED.—The everyday research of most industrial laboratories falls into this class, which corresponds to the 'investigation' mentioned previously. It aims to effect paying improvements in specified materials and processes.

The next three classes are all restricted in the methods they may employ, and only possess freedom in the minor degrees. It will be seen that the latter are not in themselves sufficient permanently to characterise work as scientific research, and the examples are correspondingly vague. It is not in human nature to study without some speculation as to 'the good of it,' which provides an aim and alters the class. These three may be termed the 'unstable classes,' where true research merges into technicality, and 'gadgeteering.'

(*e*) RESTRICTED IN METHOD, BUT FREE AIM AND SUBJECT.—The usableness of a new discovery is investigated, such as Röntgen's rays, or the emission of electrons from a hot wire.

(*f*) RESTRICTED IN METHOD AND SUBJECT, BUT FREE TO ANY AIM.—This class might be termed that of intelligent technical benevolence. It is obviously a temporary phase through which much research passes in the course of its development.

(*g*) RESTRICTED IN METHOD AND AIM, BUT FREE IN ITS SUBJECT.—Most patented inventions deal with some particular way of achieving something; the invention itself may be applied to many different industries.

The remaining class is again clear-cut in its severe limitations.

(*h*) NO DEGREES OF FREEDOM.—Testing rooms; works-control laboratories; such routine work as that done by junior assistants.

If it be agreed that these classes cover the whole range of pure and applied research, and that they differentiate between types of research which are not easily distinguished otherwise, it remains to provide them with terminology. Having regard to the varied meaning which has already been given to most of the available English words, it is perhaps better not to attempt to name each class, but to specify it when need arises as 'completely free (or restricted),' or else as 'free (or restricted) in (one respect) only.' This

covers all the eight descriptions, if only one function is specified in the latter form.

For written notation we can use capitals and small letters. 'The MSa class of research' would be our class (*c*) above. It is for this convenience that the words subject and aim are used instead of material and object, or subject and object.

Using these notations it is possible to avoid a great deal of ambiguity when industrial research is under discussion, whether inside or outside the ranks of scientific workers. Further shades of meaning could of course be obtained by defining the amount of restriction, beyond the bare positive and negative here used, but it seems quite needless at present to do so.

W. LAWRENCE BALLS.

Royston, Herts.

Science and Psychical Research.

PERHAPS I may be permitted to offer a few comments on Dr. R. J. Tillyard's article under this heading in NATURE for July 31. Dr. Tillyard's sympathy for the scientific men who take up the study of psychical research, and thus, as he complains, 'lose caste' and undergo persecution from their fellows, may appear pathetic, and his stated determination, in spite of all consequences, to join the noble army of martyrs, may even seem heroic. He may take comfort, however, in the reflection that, after all, Crookes's spiritualistic activities did not prevent him from attaining to that highest of scientific positions, the presidency of the Royal Society, nor to-day does Sir Oliver Lodge cease to remain highly honoured amongst all scientific men for his physical investigations, and especially for his pioneer work in wireless telegraphy, nor does he cease to be in the greatest request as an exponent of the most recondite theories in modern physics amongst all the best-known scientific societies and institutions.

Dr. Tillyard appears to be surprised at the attitude towards spiritualism adopted by most scientific men, but surely this is to be explained by just such expositions of the subject as Sir Arthur Conan Doyle's "History of Spiritualism." As Dr. Tillyard himself admits, psychical research is therein "most certainly very unscientifically handled." Indeed, this so-called history is no more a scientific book than its imaginative author's recent spiritualistic novel. It is replete with what has been rather aptly described as 'determined credulity," and, like most of the fantastic and amazing literature that emanates from psychic bookshops, it trades on the credulous side of human nature, and especially on the emotions of those who, having lost friends who were dear to them, are distressed at the uncertainty of the survival of human personality, and, like the drowning man in desperation will clutch at any floating straw.

Dr. Tillyard makes light of the fraudulent aspect of spiritualism, and says that fraud exists in all branches of human affairs. I can offer no opinion upon the suggestion of biological fraud to which he refers, but speaking for physics, with which I am better acquainted, I cannot remember any case of such a kind worth mentioning during my lifetime. On the other hand, the whole history of spiritualism simply reeks with fraudulent deception. There appears to have scarcely been a single well-known spiritualistic medium who has escaped criticism of this nature. The pages of Sir Arthur Conan Doyle's book are filled with the achievements of spiritualists against whom fraudulent practices have been alleged, as it would seem to the unbiassed critic, on very convincing grounds, and quite a considerable portion of the history is devoted to explaining away these unfortunate lapses, the explanation in some cases consisting of the amazing suggestion that though evidence showed that the medium did cheat on certain occasions, on other occasions no signs of cheating on the part of this particular medium could be discovered, and therefore the manifestations produced must be considered to be genuine!

The fact is that the whole basis of spiritualistic investigation, as usually carried out, puts a premium on fraudulent practices. The so-called mediums that appear to be requisite in order to conduct the experiments, seem for the most part to be persons of inferior intelligence and education. Most of them are also needy, and eke out a precarious existence by payments for their services, which payments will only continue so long as they succeed in producing extraordinary manifestations.

Imagine for a moment research in ordinary physics made under such conditions as these, with the physicist unable to carry out his own experiments and make his own observations without dependence on the aid of assistants whose interests were all the time to fake the experiments and thus obtain startling effects, assistants, moreover, whose fraudulent delinquencies when discovered were excused and explained away, as seems to be the usual practice in the case of mediums caught cheating. Could any one have confidence in the accuracy of physical investigations carried out under such conditions?

But, says Dr. Tillyard, "we who have seen these things done under conditions precluding deliberate fraud, are not fools, but in full possession of keen faculties." Does he not know, then, that the experienced medium, just like the expert conjurer, both of whom prescribe to a large extent their own conditions, will fool the observer, however acute and scientific, nearly every time? Did he never, when young, attend at Maskelevne and Cook's home of mysteries at the old Egyptian Hall in Piccadilly, and did he ever once find out how the marvellous phenomena there shown, admittedly by pure trickery, were produced?

How even the most distinguished scientific men can be deluded is evidenced by the well-known case of the "N" rays, for the discovery of which the French Academy of Sciences presented a gold medal to Prof. Blondlot, who, however, was neither a fraudulent medium nor a conjurer, but a well-known and highly respected physicist, who, as is now understood, was at the time of his discovery unfortunately afflicted by incipient insanity, from which he afterwards died. How the "N" ray myth was for ever exploded was recounted by Prof. R. W. Wood in NATURE, and is a case of genuine delusion that in the interests of truth should never be forgotten. It is a warning for all time demonstrating the extreme danger of accepting the objective reality of phenomena which, as is claimed, can only be observed, attested, or produced by particular individuals, such as so-called spiritualistic mediums, and not by all competent persons.

I have recently had some personal experience of spiritualistic methods which show how little reliance can be placed upon the support that Sir Arthur Conan Doyle gives to spiritualistic phenomena. Having read in the *Morning Post* that Sir Arthur had exhibited at the Queen's Hall a photograph purporting to be the ghost of the second Viscount Combermere, who was my uncle by marriage, I remembered that I had seen this photograph shortly after it was taken some thirty-five years ago, and that it bore no recognisable resemblance to the deceased Viscount, whom I had frequently seen and

whose genuine photograph I happened to possess. I therefore publicly challenged Sir Arthur Conan Doyle to reproduce in the *Morning Post* the alleged ghost photograph alongside the genuine portrait, whereupon he appears to have suggested to the editor of the *Morning Post* that the ghost photograph could not be reproduced for technical reasons. This assertion was promptly refuted by the *Daily Sketch*, which—I having meantime obtained a copy of the ghost photograph—reproduced with great perfection both this and the authentic portrait in the issue of that paper for May 28 last. There these reproductions remain as evidence that any one can consult, and as I think all sane persons will admit, form a complete exposure of this particular spiritualistic myth.

Ex uno disce omnes.

A. A. CAMPBELL SWINTON.

40 Chester Square,
London, S.W.1,
August 9.

I WOULD like to thank Mr. Campbell Swinton for his letter criticising my article on "Science and Psychical Research" in NATURE for July 31 last. With what he says on the subject of spiritualism I agree almost entirely; but I had hoped that my article drew a clear distinction between spiritualism and psychical research. Unfortunately, the two are evidently confounded in Mr. Swinton's mind, though they are as distinct as, let us say, astrology is from astronomy, or alchemy from chemistry. If a physicist thought of taking up astronomy, would he read up a text-book of astrology to gain his first ideas of the subject? Or if he desired to study chemistry, would he begin with a history of alchemy? Yet this is just what such a man would be doing who thought to find in a book like Sir Arthur Conan Doyle's the elements of psychical research. Let me recommend to Mr. Swinton instead the careful perusal of Prof. Charles Richet's work "Thirty Years of Psychical Research."

That I in any way make light of the fraudulent aspect of mediumship I must emphatically deny. I think that the last sentence in the concluding paragraph but one of my article supports this denial. Mr. Swinton's remarks about mediums and psychical experiments show an entire misapprehension of the essentials of the problem. Mediums may be good or bad, just like chemical balances or microscopes, Some of them are below the average level of intelligence, others greatly above it; some may be paid for their services (and why not, when, like everybody else, they have to live?), and some never take a penny for the whole of their life's work.

These things, however, are entirely beside the point. In psychical research the medium is not one of the experimenters, as Mr. Swinton seems to think, but takes exactly the same place as the spectroscope in the study of light, or the microscope in the study of minute forms of life; that is to say, *the medium is the instrument through which the phenomena become objective to the experimenters.* Usually the medium is in deep trance and knows nothing of what is occurring. The only difference between the spectroscope and microscope on one hand and the medium on the other is that one is a man-made mechanism, the other a living being (if, as many materialists aver, both are merely mechanisms, then this difference vanishes). It is easier to control the mechanism than the living being, and that is why more stringent precautions are required in psychical research than in other sciences. If a spectroscope is found to give untrue results, it is thrown aside and a more trustworthy instrument is substituted; if a medium is found to be fraudulent, then the genuine psychical researcher will not proceed with him, but will endeavour to find a more trustworthy one. The spiritualists may make his apologia if they wish; that is no concern of psychical research.

Of all the great scientific men who have patiently and untiringly studied these phenomena—Crookes, Lodge, Richet, Flammarion, Wallace, Barrett, and others—can Mr. Swinton name a single one who has not become convinced in the end of their genuineness? On the other side we have either (*a*) some few who, having met with a fraudulent medium at the start, have adopted Mr. Swinton's motto *Ex uno disce omnes*, and have concluded, *without further investigation*, that the whole business was fraudulent, and (*b*) the great majority of scientific men, who have never experimented in the subject at all, but some of whom, nevertheless, consider themselves quite competent to pass a hasty judgment upon it. My article was simply a plea for a more scientific and logical attitide of mind from this second class. *Ex uno disce omnes* may be good Latin but it is bad logic; the hasty generalisation from insufficient facts is still, as always, the curse of modern science. A great teacher once chose twelve disciples; one of them turned out a fraud and betrayed his master. *Ex uno disce omnes?* Were all the apostles frauds because of Judas' defection? Surely not! If we must have a Latin motto, let us have a logical one, such as *Humanum est errare*; then, remembering that this applies equally well to physics, biology, or psychical research, let us make our dispositions for the detection and elimination of fraud and get on with the work.

If Mr. Swinton is really in earnest in desiring to do this, I would advise him to get into touch with my friend Mr. Harry Price, director of the National Laboratory for Psychical Research, 16 Queensberry Place, S.W. 7, and make an appointment to see over the laboratory. If his inspection proves satisfactory, perhaps he might even care to go further and arrange to be present at a sitting with a genuine medium like Stella C., when he might succeed in discovering the real reason for the peculiar behaviour of the thermograph during the production of psychic phenomena accompanied by cold breezes.

External Capillary Action.

WHEN a glass tube, 6·5 mm. in external diameter, 5 mm. in internal diameter and of any convenient length, one end of which has been drawn out into the form of a cone 55 mm long with a hair-like apex 0·1 mm. in diameter and a correspondingly small aperture (Fig. 1 (1)) is filled with water containing, say, 1 per cent. of caustic soda, and held with its point downwards at an angle of 35° above the horizontal, a minute stream of water issues from its aperture, turns round underneath its lip and ascends to a distance of 33 mm. on its outer side in the form of a series of minute, disconnected, elongated globules which appear to encircle it. In flowing upwards these globules gradually lose their identity, and finally coalesce with each other to form a substantial drop at a point where the diameter of the cone is about 2 mm.

The drop encircles the cone symmetrically when the tube is vertical, but hangs from its lower side, as shown in (2) when the tube is held at an angle. After the drop has attained a weight of about 0·0113 gm.

with the tube shown, it breaks away from the influence of the force which has been holding it, sweeps swiftly down the lower part of the cone, carrying away the ascending globules, and falls from its apex. Immediately afterwards a similar series of globules begins to ascend and another drop is formed and falls away like its predecessor, and so on continuously. The weights of the drops and the rate at which they are formed vary with the angle of the tube, the magnitude of its aperture, the form of the cone, the magnitude of the head, and so on. With the tube shown in (1) a drop weighing 0·0113 gm. was formed every 2 m. 20 sec. for 12 consecutive hours in one trial. (2) was photographed instantaneously while the globules were in the act of ascending the stem.

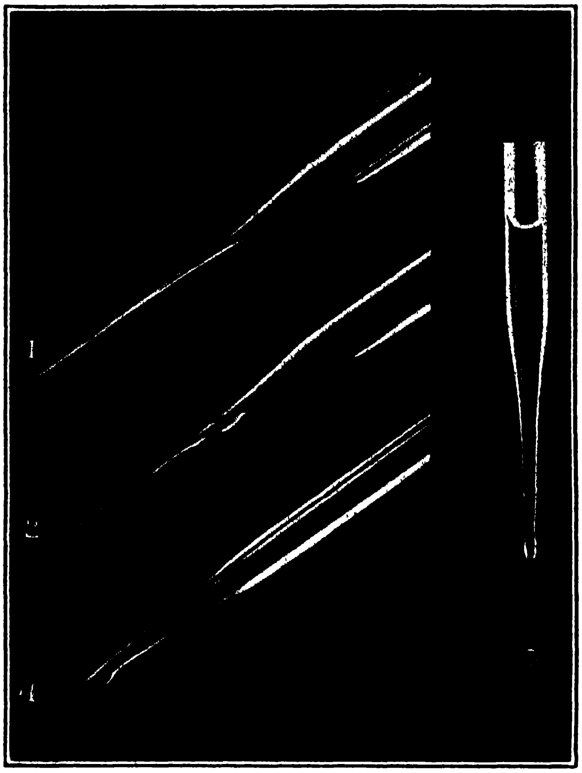

FIG. 1 - Scale, full size.

With some tubes, and some heads, the globules run up the wet surface of the cone so rapidly as to make it quite impossible to count their number; with others, and in different circumstances, they follow each other at distances of several millimetres apart at a comparatively moderate rate, according as the head is greater or less

(3) shows a tube held in a vertical position, (4) shows it held at an angle. In the former the drop encircles the cone symmetrically, in the latter it has gravitated round to the lower side.

The force which draws the water up on the *outside* of the cone in opposition to the force of gravity is obviously a function of the gradually increasing mass, and consequently of the gradually increasing attraction, of the cone.

The ratio of the weight of the salt to the weight of the decrement in the columns of solution of some salts is a *constant*. The ratio of the square root of the molecular weight of some salts (multiplied or divided by 1, 2, or 4), to the square root of the molecular weight of water multiplied by 4, is equal to the ratio of the weight of each of the same salts contained in its solution in water in a capillary column, to the weight of the decrement in water in the same column. W. GALLOWAY.

Cardiff.

Scattering of Electrons in Ionised Gases.

IN the November 1925 issue of the *Physical Review*, Langmuir published an investigation under the above title. From the collector characteristics of a mercury vapour discharge with a hot cathode, it was concluded that, in the tube, electrons must have been present with abnormally high velocities. Langmuir expressly mentions that with these discharges no oscillations could be found. In several experiments which were made by me in consequence of this publication, oscillations could in fact be detected. In accordance with my results, summarised below, it does not seem impossible that the observed "scattering of primary electrons" is always accompanied and caused by these oscillations.

1. A small metal plate, connected to a crystal detector, was placed in the immediate neighbourhood of a tube, similar to the one used by Langmuir. A galvanometer, shunted by the crystal detector, showed a deflexion at the larger current densities, when the electron velocities became abnormal.

2. To screen off the influence of the glass walls a tube was built in which the anode completely surrounded the filament. Only a few small holes (diameter 0·5 mm.) were drilled in it, in front of a collector. In this tube also the velocities became abnormal at the larger current densities, when again simultaneously oscillations could be detected. With appropriate values of emission, anode voltage, and pressure, these oscillations could be brought on a Lecher system. As wave-lengths, values from 40 cm. to 100 cm. were obtained.

3. A similar tube was used for experiments with argon. Here also, under favourable conditions, the Lecher system could be used and showed wave-lengths of the same order of magnitude.

4. With the argon experiments under certain conditions of pressure, etc., it was observed that the steady state of the discharge was only reached a considerable time after the anode voltage was switched on. During the first few minutes, neither abnormal velocities nor oscillations could be observed. Then suddenly the final state was reached in a discontinuous way. At this moment, the electron velocities became abnormal (max. about 20 volts), and simultaneously the detector galvanometer showed a deflexion.

5. Finally, the relation between the abnormal velocities and the distance through which the electrons had gone was investigated. With a tube as described under (2) above, the collector of which could be moved, it appeared that the electron velocities did not become more and more abnormal with greater collector distances, but the reverse happened. This also is not in agreement with the explanation suggested by Langmuir.

A more detailed description of the experiments will be published in the Dutch periodical *Physica*.

On the Law of Radiation.

THE view of physicists on the question of distribution of black-body radiation is that the equipartition principle cannot apply to the problem, and that "each step from matter to ether, or back again, demanded the quantum factor, and does demand it wherever such interaction occurs," as Sir Oliver Lodge recently expressed it in NATURE, June 26, p. 891.

In the session of February this year I presented to the Pontifical Academy of Sciences, Rome, what I think is a new method of attacking the problem, on the basis of equipartition, with only the hypothesis that frequencies are distributed in the same way as velocities in Maxwell's law for gases

If we express the probability that frequency is between the limits ν and $\nu + d\nu$ by

$$\theta(\nu)d\nu = Ce^{-a^2\nu^2}\nu^2 d\nu,$$

where $C = \frac{4a^3}{\sqrt{\pi}}$, the corresponding number of oscillators will be

$$dn_\nu = N\theta(\nu)d\nu = \frac{4a^3N}{\sqrt{\pi}}e^{-a^2\nu^2}\nu^2 d\nu,$$

N being the total number in volume unit, and the density of energy in the emitting body, on the basis of equipartition

$$u_\nu d\nu = \chi TN\theta(\nu)d\nu = \frac{4a^3\chi TN}{\sqrt{\pi}}e^{-a^2\nu^2}\nu^2 d\nu.$$

Thence follows the expression for the emitted energy $k_\nu d\nu$; and assuming the Stefan law for totality of energy, it is easy to deduce $N = \frac{8\pi\sigma T^4}{\chi T c}$, σ being Stefan's constant, and therefore for k_ν the expression

$$k_\nu d\nu = \frac{4a^3\sigma T^4}{\sqrt{\pi}}e^{-a^2\nu^2}\nu^2 d\nu.$$

In order to calculate the constant a we transfer the expression for k_ν in the corresponding E_λ through the relation $E_\lambda d\lambda = k_\nu d\nu$ and introduce Wien's law of displacement. The expression for E_λ becomes

$$E_\lambda d\lambda \quad \frac{4a^3}{\lambda^5\sqrt{\pi}}\lambda T e \quad d\lambda,$$

where a is Wien's constant multiplied by $\sqrt{2}$

The law of distribution hence will be

$$F(\lambda,T) \quad \frac{4a^3\sigma}{\lambda^5\sqrt{\pi}}\lambda T e^{-\frac{\quad}{\lambda^2T^2}}$$

corresponding to Wien's condition, and containing only the Wien's and Stefan's constants. When λT is large the formula reduces to Lord Rayleigh's expression

The new formula agrees very satisfactorily with the measured energy distribution in the solar spectrum.

The Electrical Polarity of Molecules.

ON attempting to correlate the electrical double-refraction (Kerr effect) of gases and vapours which has been measured by Leiser, Hansen and Szivessy, with the optical anisotropy of the molecules determined from observations on light-scattering, it is found that electrically polar molecules generally exhibit a Kerr effect which is very large in relation to their optical anisotropy. This indicates that the orientative action of the field on the molecule in such cases is chiefly due to the permanent electric doublet present in it, and is much larger than would be the case if the molecules were non-polar. In the case of molecules having an axis of optical symmetry to which the electric doublet is parallel, or is inclined at some known angle, it is possible to calculate the permanent electric moment from the value of the Kerr constant and the constant of depolarisation of the scattered light. Conversely, if the moment is known, the inclination of the electric doublet to the optic axis can be found. For example, in the case of the simple dipole molecule HCl, we may assume the optic axis to be parallel to the doublet.

The constant of depolarisation as recently measured by Ramanathan is 0·010, and the Kerr constant from the measurements of Hansen $0{\cdot}90 \times 10^{-10}$. From this, considering the orientative action of the field to be due only to the permanent doublet, we find its moment to be 1·06 electrostatic units, while if the orientative couple on the induced doublet is also taken into account as in the case of non-polar molecules, the value of the permanent moment comes out to be $1{\cdot}04 \times 10^{-18}$. The recent determination by Zahn from dielectric constant measurements gives $1{\cdot}03 \times 10^{-18}$, thus showing good agreement.

When the optical ellipsoid of the molecule has three unequal axes, measurements of the factor of depolarisation and of the Kerr constant are by themselves insufficient for an accurate determination of the electric moment. But if the moment is known from measurements of the dielectric constant, the data mentioned are of much assistance in fixing the position of the axis of the doublet. For example, if the Kerr constant of a substance is negative, we can assert definitely that the axis of the permanent doublet does not coincide with the longest axis of the optical ellipsoid. It is interesting to note in this connexion that, so far as is known, all substances having a negative Kerr constant are polar.

Depth of Origin of the Earthquake of August 15.

THE earthquake of Sunday morning, August 15, was one of those for which no method of determining the depth of origin had been devised until recently, and offers an opportunity for applying that which was published in the *Quarterly Journal of the Geological Society* for February last. The extreme limits of the area over which the shock was felt appear to have been Llandrindod Wells and Blackheath, which are about 150 miles apart; the maximum violence seems to have just about reached the lower limit of VI° of the Mercalli scale, or an acceleration of about 150 mm./sec.² Applying the coefficients in the paper referred to, the resulting depth of origin is not far from thirty miles. This estimate is based on the newspaper reports and subject to correction when more precise data are available. The maximum acceleration may have been more than the figure adopted, the limiting value of acceleration, of a shock which is just sensible in England, may be less than the 20 mm./sec.² adopted, and either of these would lessen the resulting depth of origin. On the other hand, the description of the shock at

the limiting stations suggests that it must have been sensible even beyond them, and this would give a greater depth. Taking all these circumstances into consideration, it seems probable that the earthquake originated at a depth of some 25 to 30 miles, say 40 to 50 kilometres, below the surface of the ground.

R. D. OLDHAM.

The Groma: an Ancient Surveying Instrument.

A FEW weeks ago, while looking through some miscellaneous objects at the premises of the Egypt Exploration Society, I discovered a portion of a groma, an ancient surveying instrument, commonly used in Græco-Roman times for setting out straight lines and directions at right angles, in building operations as well as in land instruments.

There are several references to this instrument in the literature, but the only other specimen known was one unearthed at Pompeii in fragments in 1912. This was reconstructed by M. Della Corte and a model is in the South Kensington Museum. There is a representation of a groma on the tombstone of a Roman 'Mensor' found in the neighbourhood of Turin.

The portion now brought to light consists of two roughly shaped pieces each about 12 inches in length, formed of the centre rib of a datepalm leaf, bound together at the centres by a lashing of datepalm fibre, forming a loop for suspension. Near the ends of each piece are in-cuts to locate the plummet strings which were suspended from the ends.

So far as is known, this is the first specimen of the kind known, and special interest attaches to the fact that it came originally from Egypt, having been brought from the Fayum in 1899. Since then it has lain unrecognised among the Museum surplusage in the Society's basement. It probably dates from the Græco-Roman period and may be a tomb model.

The specimen has been acquired by the South Kensington Museum authorities and will shortly be exhibited there.

The Absolute Density and Coefficient of Expansion of Silicon Tetrachloride.

IN a recent paper on "A Comparison of the Atomic Weights of Silicon from Different Sources" (*Jour. Chem. Soc.*, 1926, **128**, 1262) the density of silicon tetrachloride from different sources was determined by means of glass floats. These were calibrated at one temperature and used in the actual measurement at another, but in making the calculation we omitted to take into consideration the alteration in volume of the floats consequent on this change in temperature. After we had instituted inquiries for a trustworthy coefficient of thermal expansion for the 'Durosil' glass used, in order to correct the reported figures, we received a private communication from Mr. A. G. Milligan pointing out this omission, which leads us to take this early opportunity of publishing a provisional correction. Applying the probable value $14 \cdot 1 \times 10^{-6}$ for the cubical expansion of 'Durosil' to the data already published (*loc. cit.*), the mean density and coefficient of thermal expansion of silicon tetrachloride become $1 \cdot 481461 \pm 0 \cdot 000020$ and $0 \cdot 0014048 \pm 0 \cdot 0000022$ respectively. We hope to publish elsewhere a complete résumé of the densities, etc., when our inquiries have yielded a trustworthy coefficient of expansion for this glass.

It should be noted, however, that the application of this correction to the five densities in question makes no alteration in their relative magnitudes, and thus leaves unaffected the essential conclusion of our paper (*loc. cit.*).

The Movements of Molecules.

IN a very interesting little book on phosphorescence by T. L. Phipson, Ph.D., published in 1866, on p. 184 he says: "We have no proof that the molecules of bodies vibrate in straight lines; their motion is more probably circular. Indeed, my ingenious friend, M. Porro, has endeavoured to show the great resemblance which seems to exist between these molecular movements and those of celestial bodies; and it has been supposed by some philosophers that the molecules of matter are as distant from each other, in proportion to their size, as the planets themselves." "But in the present state of knowledge, all these considerations are premature."

Ignazio Porro (1795–1875) was a French physicist who made improvements in the binocular telescope, the telemeter, and other optical instruments. It would be interesting to know if he had any inkling as to the existence of moving particles or electrons in atoms. I have looked through the list of his published papers given in the Royal Society Catalogue, but did not see any titles which appeared to bear upon the subject; perhaps some readers of NATURE may know of some which do.

Pernicious Grafting.

To reply fully to the question asked by Dr. Grabham in NATURE of July 17 would entail a much greater demand upon the space available than the subject would at present appear to justify.

A study of the question as set forth by Dr. Grabham immediately suggests to the practical cultivator that root control would remedy the evil: nobody expects the best results from peach or nectarine trees grafted on any stock unless systematic root pruning is practised, and from the tendency of the wild 'individuals' in Madeira to flower before the fall of the leaf one adduces the fact that there is a lack of sympathy between stock and scion; therefore root pruning might be the means of modifying the flow of 'incompatible' sap to the need of the cultivated variety at that period. Moreover, a cool moist condition of the soil during the winter being essential to successful peach cultivation, it may be necessary to adopt means of providing these conditions in Madeira, as well as a careful selection of root stocks.

The Relation between Cultivated Area and Population.[1]

By Sir DANIEL HALL, K.C.B., F.R.S.

RECENT considerations of the problem of the capacity of the world to continue to feed its growing population appear to have begun with the late Sir William Crookes's address as president of the British Association when he discussed the ultimate curtailment of the wheat supply through exhaustion of the soil nitrogen. Crookes's views attracted little more than academic attention at the time (1898) because the great tide of wheat that was setting in from the newer countries still in the process of exploitation was barely slackening; moreover, Crookes had neglected a factor then imperfectly appreciated—the fact that land under any of the conservative systems of farming adopted in the old settled countries does not become exhausted. Generally speaking, a soil will remain itself indefinitely at a certain level of production. Latterly in Europe that level has been raised by the introduction of extraneous fertilisers. In his review Crookes predicted the development of the synthetic processes of bringing nitrogen into combination which are to-day rendering that prime element of fertility so abundant and so cheap.

Though we no longer fear the exhaustion of soils, of late years certain sociological considerations have revived interest in the old thesis of Malthus. Over-population and unemployment have become terrible realities in Great Britain and other countries; many States are finding themselves under pressure to maintain their standard of living against the intrusion of neighbouring races propagating recklessly down to the barest margin of sustenance. Again, various studies of the course of prices of wheat have led to the conclusion that before the War the real price was rising continuously, and that this tendency is manifesting itself again, however much the true sequence of prices has latterly been obscured by fluctuations of currency.

These considerations led Mr. Keynes to envisage the approach of scarcity: his attitude is very much a return to Malthus. On the other hand, Sir William Beveridge, addressing the Economics Section two years ago, dismisses this fear as regards the world at large; whatever may be the troubles in Britain, "the limits of agricultural expansion are indefinitely far." On the whole that seems a very safe proposition; it has been so amply fulfilled for the last hundred and fifty years—during the greatest expansion of population the world has ever known—that it would almost seem to be necessarily true, especially as it can be buttressed by agricultural experiments showing the enormous potentialities of production from the soil.

There is, however, one aspect of the case that appears to have received insufficient attention: the capacity of agriculture to provide food for the people depends upon the extent of land available as well as upon the pitch of cultivation. To what degree can the tuning-up of methods be made to compensate for a non-expanding acreage? The first step towards a more exact consideration of the problem may therefore be an estimate of the amount of cultivated land that is required to maintain one unit of population—man, woman, and child.

We may make our estimates by either of two methods—abstract or actual. The Food (War) Committee of the Royal Society adopted the figure of 2618 calories as representing the minimal daily energy requirement of one unit of the population, and calculated that the actual United Kingdom consumption in the five years 1909–1913 amounted to 3091 calories per head per day. An average English acre of wheat yielding 32 bushels will produce food, in the shape of wheat, flour, and pig obtained from the offals, of a calorie value of about $2\frac{1}{2}$ millions. As the average consumption was about 1·13 million calories per head per year, we arrive at the conclusion that one acre of wheat would support more than two head, the relationship being more exactly 0·45 acre to feed one unit of population. But this figure is of no service in our more general consideration. The yield of wheat of 32 bushels per acre is far above that of the wheat-producing areas, and is that of only a few selected countries growing but a limited acreage. It is again the produce of land under the plough, and is consumed in the main as a vegetable product.

The great areas of grassland have a lower output of energy than the cultivated land, and the conversion of vegetable into animal food, whether of natural or cultivated fodder crops, is always attended by a great waste of energy. In the most economic production of pig-meat or milk, the energy recovered is only about one-sixth of that consumed, and this represents the machine at the top of its efficiency. The longer period of beef production results in a recovery as beef of only one-eighteenth of the energy consumed, and in practice the actual wastage of fodder and feeding-stuffs doubles or trebles the inevitable losses by conversion. Moreover, just as man is not a vegetarian making the most of the mere sustaining power of the land, so he does not use the land for food alone, but also for drink, for wool and fibre and other industrial materials, and for amenities.

We shall not get far on the theoretical basis, and I have only mentioned it as indicating the order of the superior limit of the maintaining power of land.

THE UNIT OF MEASUREMENT.

We must approach the question in a more empirical fashion and endeavour to ascertain the existing relation between the land in use and the people fed by it. Taking again the estimates of the Royal Society's Committee, it concluded that the United Kingdom production of food for the five pre-War years was 42 per cent. of the food consumed; 46·7 million acres of cultivated land then produced 42 per cent. of the food consumed by a mean population of 45·2 millions, which works out to 2·5 acres to each unit of the population. This figure, however, is somewhat misleading in that it does not do justice to British agriculture, since our farming is to a considerable degree concentrated on the more costly elements of diet like meat or milk rather than upon cereals and sugar. For example,

[1] From the presidential address to Section M [(Agriculture) of the British Association, delivered at Oxford on August 9.

49 per cent. of the food production at home, as against only 24 per cent. of the imported food, consisted of animal products.

The importance of this relation between cultivated area and population is so great, and the calculations by which it can be ascertained are so approximate and subject to so many estimates of a speculative kind, that I may be allowed to set out various results obtained by different methods.

We may begin by comparing population and area of cultivated land for all European countries except Russia, to which we add the United States, Canada, Argentine, Australia, and New Zealand, as the white countries which are also the chief exporters of food to Europe. I exclude all oriental countries because in them the mass of the population possesses a different standard of living, and I have excluded the other South American States and the Union of South Africa and other African colonies because they all possess a very large 'native' population and their exports do not bulk large in the food account of Europe. We must recognise, however, that the errors in the calculation will be loaded on to one side, because all the unenumerated countries, Russia and the tropical lands, are to a greater or less degree exporters and not importers of food. However, with this proviso we find that in the States enumerated there are 464·1 million hectares of land under cultivation and a population of 481·5 million persons, or 2·4 acres per head.

In the United States about 356 million acres are in cultivation: from this may be deducted as producing exported materials, for cotton 24, for wheat 16, for maize 2, for meat products 22 million acres, or 65 million acres in all. Other products are exported but may be regarded as balanced by imports, so that we find 291 million acres of cultivated land devoted to supplying a population of approximately 112 millions, or 2·6 acres per unit of population.

France we know is a country that is largely self-supporting; it has a population of 39·3 millions and 36·3 million hectares under cultivation. To this acreage we must add 0·9 million for imported wheat, 0·5 for other cereals, and 1·1 for imported meat; the exports of wine and fruit we may regard as balanced off by other imports. The net result is approximately 1 hectare, or 2·4 acres, for each head of the population.

A similar calculation applied to Spain, a country in the economy of which neither exports nor imports of food play a large part, gives more than 4 cultivated acres per unit of population; but then the so-called 'cultivated' land includes a considerable proportion of mountain pasture of a very low order of productivity. On the other hand, Denmark, with the most highly developed agriculture of all countries, shows a production well above the average. A much closer calculation of production is possible for Denmark than for other countries—the data are set out in Mr. Harald Faber's paper before the Royal Statistical Society in 1924. Denmark is a country exporting agricultural produce chiefly in its most costly form as meat, butter, and eggs, but the means for equating the export against consumption is supplied in Mr. Faber's paper by the reduction of production and imports to food units. Making the necessary corrections for imports, it would appear that for the years 1909–1913 the population of Denmark was maintained on 63 per cent. of the production of her own land, or 1·82 acres per person.

Putting the various estimates together, we arrive at the conclusion that under the existing conditions of agriculture among the Western peoples, it requires something between 2 and 2½ acres of cultivated land to supply the needs of one unit of population living on the standard of white peoples.

We may confirm this estimate by a consideration of the growth of population during the last century. Between 1800 and 1920 the number of the white peoples increased from about 200 millions to about 700 millions. Data, however, for the land under cultivation in 1800 are very imperfect, and again there was another factor of improved agriculture which came into play in the first half of the nineteenth century. If we take 1870 as our jumping-off point, we may estimate the increase in the white man's numbers up to 1920 as approximately 225 millions. During the same period the addition to the cultivated lands in Europe, United States, Canada, Argentina, Australasia, and South Africa, the countries which have provided the white races with food, has amounted to about 450 million acres. Again we reach a relation between cultivated land and population of between 2 and 2½ acres per head.

This brings me to the central point of my argument, that an increase of population is in the first instance dependent upon an increase in the area of cultivated land. The expansion of the white peoples in the last century was an event unprecedented in the world's history, and was achieved only because of the vast areas of unoccupied land, chiefly in the Americas, which suddenly became available for settlement through the power conferred by the railroad, the steamship, and modern weapons. It will be noticed that the population of Europe previously had become comparatively stable, even as it has become approximately stabilised in France at present—the expansion came with the opening up of the new lands and in proportion to the amount that could be settled.

ENERGY VALUE OF PRODUCE.

Accepting as a basis for further discussion that under the present system of agriculture something more than two acres of new land will have to be brought under cultivation for each unit of increase in the population, we may examine if any means exist of modifying this relationship before considering its consequences.

I have already suggested that a vegetarian diet is the more economical of the resources of the soil, and that meat and all animal products like milk and eggs are produced with an expenditure of energy which may be so low as seven but also so high as twenty times the energy available from them. It is true that to a certain extent the animal will utilise material otherwise of little service to man, like milling offals and low-grade fodder crops—roots, hay, or straw. None the less, if the maximum of population supported by a given area of land is the objective, vegetarianism becomes increasingly necessary, as we see among the crowded populations of India and China. At the same time, the tillage of lands now given up to the grazing of animals becomes possible because of cheapness of labour resulting from a redundant population. Most

of the beef and mutton supply comes from land left untilled because of the costliness of labour relative to products; the meat may represent a very low level of production from the land and yet a high cash return for the labour expended. Hence the apparent paradox of grazing being general in Middlesex because of the proximity of London.

Another item of waste which would have to be eliminated in case of stern necessity is the conversion of potential food into alcoholic drink. Great Britain ferments the equivalent of one and a half million acres of barley. France devotes 4,000,000 acres, nearly 4·5 per cent. of her cultivated area, to vineyards. Without going so far as to say that beer or wine possesses no food value, it is certainly not half of that which could have been grown from the land thus used for the production of drink. In such matters it is vain to prophesy, but I cannot help feeling that the race (not individuals) which cuts out meat and alcohol in order to multiply is of the permanent slave type destined to function like worker bees in the ultimate community.

INTENSIFICATION OF PRODUCTION.

The second question that merits very careful consideration is whether the current agriculture cannot be intensified so as to bring about a great increase of production from the existing area of cultivated land. A cursory examination of the average yields of our chief crops in different countries shows what an immense potential increase of production is here open. The average yield of wheat (1921 to 1924) for all the countries of the world collecting statistics was 13·2 bushels per acre; the average yield in Denmark for the same period was 41·4 bushels per acre—more than three times as much. Of course the area devoted to wheat in Denmark is about 200,000 acres in all, or 3 per cent. of her arable land, whereas the wheat acreage of the world amounts to about 250 million acres. The mass production of wheat in the world is from countries of low yield; more than half is grown in countries in which the average yield is less than 13 bushels per acre.

It is from these countries with the low yield per acre that wheat is exported, and their production determines the world market, with the consequence that wheat production has been increasing in these and similar countries, while it has been shrinking in the European countries with a higher yield per acre.

The dominating factor has been cost of labour; speaking broadly, it may be said that increased yields per acre are associated with higher expenditure per bushel for labour, and the great wheat-producing countries with a low yield per acre are the countries with a correspondingly high yield per man employed. It may be estimated that in England a man's labour produces about 960 bushels of wheat, in Australia 1500 bushels. A more exact comparison shows that in England the labour cost amounts to 1*s*. per bushel of wheat, against 8*d*. in Canada; this with an average wage rate of 30*s*. to 36*s*. a week in England as compared with 60*s*. in Canada.

All this goes to show that intensification is only to be purchased at the cost of labour, and that in the past, extending the cultivated area has been a cheaper way of getting the wheat required by the world than higher farming.

This general statement, however, does not tell the whole story; particularly it disguises the intensification of yield that may be obtained without a commensurate increase of labour. For example, the introduction of more heavily cropping varieties, originated by the skill of the plant breeder, may add greatly to the production from a given area without increasing costs other than those of harvesting and marketing.

One must not, however, expect too much of the plant breeder. Over the greater part of the cultivated land of the world the gross amount of production is limited by external factors such as water supply, temperature, available fertility of the soil, etc. For example, the wheats and barleys grown in England had long been subjected to selection and improvement before the scientific methods of plant breeding were evolved, and the further steps in improvement are going to be neither big nor easily won, depending as they do upon altering what Dr. Beaven has called the migration ratio, whereby the plant will convert more of the material obtained from the air into useful grain and leave less as straw. The chief opportunities, in fact, lie in the elimination of susceptibility to disease or destruction by frost, or general tenderness of constitution, by which means the range of the high-yielding cereals, or even of cereal growth at all, may be enormously extended.

ARTIFICIAL FERTILISERS.

The general enhancement of production by processes which induce improvements of the water supply or the temperature, as by irrigation and drainage, soil amelioration, cultivations, etc., suffers from the disadvantage of calling for labour, until it may prove far more costly than the increased produce can repay. Fertilisers appear to offer more promise. It may be recalled that the general level of production from English land was raised by nearly 50 per cent. between 1840 and 1870. At the beginning of the period the average yield of wheat was of the order of 20 bushels per acre, this being the crop the land was capable of maintaining under a conservative rotation with no extraneous source of fertility. But between 1840 and 1870 artificial fertilisers were introduced and became a generally accepted part of British farming, with the result that the yield of wheat had risen to about 30 bushels per acre, though no other marked change in the routine of cultivation had been adopted during the period. The employment of fertilisers still lags far behind the opportunities of employing them to profit.

The various processes of bringing atmospheric nitrogen into combination, to which the War gave such a stimulus, are now being developed on a vast scale in all civilised countries, and will result in an almost unlimited increase in the amount of nitrogenous fertiliser available at low prices compared with the prices of agricultural produce. Here at least is the opportunity for another step up in production from our cultivated lands comparable with the progress that was made between 1840 and 1870. It is not all

plain sailing; the farmer has to study carefully where an increased supply of the cheapened nitrogen can be most suitably applied to his land and what changes in his system of cropping are demanded. The plant-breeders' art is needed; on most of our land any great enhancement of growth of cereals brought about by the use of nitrogenous fertilisers is attended with the danger of lodging. Few of our cereals possess stiff enough straw to remain standing on a soil enriched to the degree even that is reasonably practicable to-day. Thus the more immediate outlet for the new fertilisers would appear to be the fodder crops which are convertible into meat and milk.

In the solution of the main problem under discussion—the possibility of intensification of production from the existing farmed land to meet the needs of a growing population—the development of the synthetic nitrogen fertilisers must play a dominant part. Crookes's prophecy is coming true.

THE ECONOMICS OF PRESENT-DAY AGRICULTURE.

The present annual increment in the white population may be estimated at about five millions. This, taken alone, would necessitate the taking into cultivation of twelve million acres of new land every year. No process of the kind is going on; indeed, for many crops there has been an actual shrinkage in the acreage since the War. The shrinkage is doubtless no more than a temporary matter, the back-water of the wild fluctuations of prices and values brought about by the War, but it does not promise well for that continued expansion of the cultivated area which the still growing population demands. Indeed, we may detect a new influence at work, the growing disinclination of the civilised peoples to continue in agriculture because of its small and uncertain returns as compared with those of other occupations.

The flight from the land is manifest equally among the wage-earners of large-scale agriculture and among the peasants or family farmers in whose hands resides the greater part of the cultivation, whether in the old settled countries of Europe or the newer exploitations of America. Again and again it must be urged that the determining cause is economic; for the last half-century, save for the abnormal War years, farming has not paid a return on the capital and labour expended comparable with that obtainable elsewhere. It has been said that even the American farmers of the Middle West, who cut prices for all the world, made no profits during the last half-century except those derived from the accretion of land values; and the peasant farmer, who counts neither the capital he has in the business nor the hours of labour he gives to his land, who in Europe is held to the land by secular tradition, finds agriculture unattractive so soon as the growth of industries and the spread of communications render an escape possible. If not the peasant himself, at least the sons look for an easier and less exacting mode of life.

At this stage it would be impossible to begin to diagnose the causes of the comparative unprofitableness of agriculture. Fundamentally it is due to the weakness of the farmer as a commercial unit; the smaller the farmer the more ruthlessly does he compete with his neighbours and reduce prices to a bare level of sustenance for his long hours of labour. Even the large farmers who can put into practice some of the economies of an ordered industry are helpless against the large commercial organisations which pass on their produce to the customers. Always there is the peasant farmer to cut prices.

I cannot, however, pursue this issue. I return to my original text: that if we are to continue to feed the growing population of the world on the present methods a continued expansion of the cultivated area is required; new land is called for year after year. I cannot see where this new land of the necessary quality is to be found in quantities commensurate with the immediate demand. Doubtless the white races will insist on maintaining their rising standard of living and will apply deliberate checks to their fertility, a process we already see in action. But the restriction of increase will not take effect all at once even under economic pressure, and the danger lies in the period preceding the comparative stabilisation.

As it cannot be supposed that the development of the civilised races can be allowed permanently to be checked by lack of food when food is obtainable, it follows that resort must be had to the intensification of production from the area already under cultivation. The means for that intensification are already in sight, more will be supplied with the advancement of research. Intensification, however, is in the main attended by a higher cost of production, and movement in that direction is likely to be slow until it is stimulated by a rise of prices. Organisation will have to be introduced into the industry, and it may be expected that organisation will take one or other of three forms. The farmer may be left as the producing unit, but his methods will be strictly controlled and standardised by the great selling corporations that handle his produce, and these corporations may be either commercial ventures or co-operative associations of the farmers themselves. The co-operative venture appears to imply an even more rigid discipline of the individual than that imposed by the capitalist firm. Alternatively, the capitalist may venture upon the direct exploitation of large areas of land and industrialise farming as he has industrialised other producing businesses. But capital will only be tempted back to farming, whether for the organisation of the business or even to enable the individual to take advantage of the possibilities of intensification, if prices rise to a definitely remunerative level.

I hope I have given reasons for supposing that prices must rise, because the surge in population set up by the unprecedented extension of the cultivated area last century cannot all at once be checked, whereas the new land still available is either inadequate in amount or unsuited to cheap production by the old methods. How close at hand the period of pressure may be it is unsafe to prophesy, but it may be agreed that pressure is sooner or later inevitable and that one of the biggest problems before the world at present is to prevent the pressure developing suddenly or becoming unbearable. The intensification of production is the only remedy, and, again, the only means of rendering intensification practicable is the continued pursuit of scientific research.

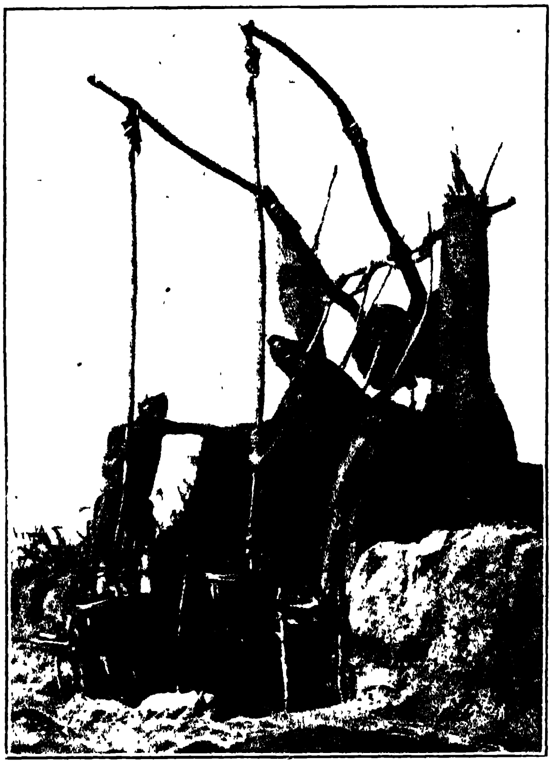
The Rate of Work done with an Egyptian Shadouf.

By Dr. J. S. HALDANE, F.R.S., and Dr. YANDELL HENDERSON.

THE shadouf is a man-power apparatus which from time immemorial has been used in raising water from the Nile or from canals, etc., for local irrigation purposes in Egypt. Great numbers of them can be seen in operation throughout all parts of Upper Egypt, and there appears to be little tendency towards their displacement by power-driven pumps.

With a shadouf water is lifted, usually about ten or eleven feet, in a goat-skin bucket, and delivered into a water-channel at the higher level. During low Nile in Upper Egypt, three shadoufs, or pairs of shadoufs, working in series, are commonly employed to lift water from the Nile level to that of the adjoining land. The bucket (Fig 1) is carried on a wooden hook lashed to a light upright pole of tamarisk wood. This pole is attached at its upper end by rope to one end of a light beam made from a branch, or two branches lashed together, of acacia wood, which is sufficiently strong and rigid to support the weight of the bucket without much bending. At about three-fourths of the distance to the lower end, the beam is pierced by a hole through which passes a wooden pin on which the beam is pivoted. This pin is suspended by short cords from a stout wooden bar, of which the ends rest on two upright pillars consisting of either wood or maize-stalks and dried mud. Round the other end of the beam is plastered a globular mass of dried mud and chopped straw to serve as a counterpoise. Acting on the short end of the beam it is sufficiently heavy (about 230 lb.) to raise a bucket-full of water suspended at the other end.

The bucket consists usually of goat-skin, although light metal buckets of similar size and shape are used in some places, and is held open by a wooden ring about sixteen inches in diameter, and has a cross-bar to which the wooden hook is attached. Since the counterpoise pulls up the water, nearly all the work done by the man is performed in pulling downwards the upright pole carrying the empty bucket. During this operation his body becomes bent to extreme flexion, and has to be straightened as the bucket ascends. He has also to tip the bucket when it reaches the higher level, and just as it reaches the lower level he gives the pole a slight jerk, so as to make the bucket enter the water edgewise, and thus fill instantly.



1.—P... f shadoufs working in parallel. After a photograph by Messrs. Gaddis and Seif, Luxor.

During a recent visit to Egypt we took the opportunity of measuring the rate of work done in raising water by means of a shadouf. All shadoufs appear to approximate very closely to the figures here reported. We found that the bucket holds about 60 lb. of water when nearly full, as in the lift, and is raised 11 feet $6\frac{1}{2}$ times a minute, or up to 8 times a minute for a correspondingly less elevation. Thus the work done in raising the water is about $60 \times 11 \times 6 \cdot 5 = 4290$ foot-pounds per minute, or nearly 600 kilogram-metres per minute. Two men, working alternately for about an hour at a time, are employed on each shadouf, and each man works for a total of about 6 hours daily. Thus the work per day is about 1,550,000 foot-pounds or 700 foot-tons. The shifts are measured by means of a simple sundial, improvised on the spot. Its essential part is a cord stretched horizontally north and south between the tops of two pegs a few inches above the ground, with marks to indicate the endings of the shifts by the progress of the shadow. The intervals between shifts are devoted to light occupation, meals, and rests.

From other well-known physiological data we may reckon that the gross efficiency of the work during the raising of water is about 20 per cent. As the work done is 1,550,000 foot-pounds, the corresponding amount of energy liberated in the body is therefore equivalent to about 7,750,000 foot-pounds, which is equivalent to almost exactly 10,000 British thermal units, or 2500 calories. This is at a rate of about 417 calories an hour, or 7 calories a minute. During the remaining 18 hours of the 24 the average energy liberated cannot well be less than 80 calories per hour, so that the total liberation of energy will be at least 4000 calories. To cover this expenditure the shadouf worker will, if we make the ordinary allowance of 10 per cent. for waste, require food of the energy-value of at least 4400 calories.

The men working on the shadoufs are erect and finely developed, looking a picture of health and physical grace, and doing the work without signs of fatigue. They take several meals daily between shifts. These meals consist usually of cakes made fresh each day from maize or wheaten flour, with cheese and sour milk. Hot meals, with lentils or

beans, and occasional meat, are taken at home. The work could not be kept up day after day if the food were not abundant. We were told that this food is almost entirely the produce of the land the men are irrigating and cultivating. The actual men who work the shadoufs and do the other work on the land are joint farmers. They thus work jointly for themselves and pay the rent jointly, taking all the produce and profits from its sale after the rent has been paid. The rents seem enormous by British or American standards, but the land, as actually worked, is extremely productive. It is very improbable that if the men were working on daily or weekly wages they would work so effectively or obtain the same net earnings. It seems also to be for essentially the same reasons that modern power-driven appliances have not displaced the shadouf. A shadouf is not only extremely efficient mechanically, but can be made from materials on the spot, and can be at any time repaired by the men who use it. To judge from carvings on a tomb near Luxor, the shadouf was practically the same more than three thousand years ago as it is now.

The work done on a shadouf is of special physiological interest, because it is so well standardised, employs so many muscles, and is so easily measured directly. In most kinds of standardised work we can only measure the work indirectly from the oxygen-consumption. In the late Mr. Jervis Smith's book on "Dynamometers" (edited by Prof. Boys) a description is given, on page 10, of another easily measured form of standardised human muscular work. This form of work was employed early last century in raising the earth needed in the construction of forts round Paris. The earth was loaded into a bucket attached to a rope passing over a pulley, and was then drawn up by the action of a counterpoise consisting of a man, whose work consisted in continuously ascending a ladder and coming down as a counterpoise to the ascending earth. It was found that the work done in this way amounted to 4230 foot-pounds per hour—a figure very close to ours for the shadouf worker as regards the rate per hour, though the French navvies kept up this rate during eight hours daily.

There can be no doubt that where the motive is adequate a man in good physical training, and fed in correspondence with the work, can keep up day after day, for say eight hours, a considerably greater rate of measured work than corresponds to these figures; and for short periods far greater rates are possible. Thus Henderson and Haggard (*Amer. Journ. of Physiology*, **72**, p. 264, 1925) found that over a four-mile race in 22 minutes each oarsman of a university crew did average measured work at a rate of 0·45 horse-power, or 15,000 foot-pounds a minute, with a total energy-expenditure of 19 calories a minute, or at the rate of 1140 calories per hour. This rate is $3\frac{1}{2}$ times that of the shadouf workers, but, of course, could not be kept up nearly so long. In a $1\frac{1}{4}$ mile rowing race the rate rose to 0·57 horse-power, or 18,770 foot-pounds a minute. For very short periods of less than a minute, still higher rates are possible, even for an untrained man. For example, Douglas and Haldane, with the view of producing maximum discharges of lactic acid from muscles during their temporary lack of oxygen, used short bursts of climbing work at a rate of 30,000 foot-pounds per minute (*Journ. of Physiology*, **38**, p. 431, 1909). The rates of work of the shadouf men and of the French navvies are, however, worthy of record, as these rates could, without unusual effort, be maintained day after day throughout the working period.

We have pleasure in acknowledging the help we received from Mr. George Gattas, of Luxor, a chief dragoman on Messrs. Cook's Nile Service steamers.

Audibility of Explosions and the Constitution of the Upper Atmosphere.

By F. J. W. WHIPPLE.

PHYSICISTS who are interested in the problem of the temperature and constitution of the upper atmosphere have been awaiting with some impatience the publication of the official reports on the audibility of the experimental explosions arranged by the International Commission for Investigations on the Sound of Explosions. The first experiment was made (at Oldebroek in Holland) in October 1922, but the full report on the second experiment or series of experiments has appeared first. This report[1] has been prepared by Prof. Charles Maurain, head of the Institut de Physique du Globe at Paris. Some idea of the mass of evidence that has been digested may be gathered from the facts that 405 observations were plotted on the map showing the audibility of the first explosion, 360 and 240 on the maps for the second and third.

The site of the explosions was at La Courtine; this place is about half-way between Paris and the Pyrenees; as it is more than 250 km. from the nearest sea, the audibility in all directions could be investigated. There were four explosions, on May 15, 23, 25, and 26, 1924. In each of the first two, about ten tons of melanite was spent, in each of the others, five tons. Observers did not receive sufficient warning in the last case, and M. Maurain's report is practically confined to the other three.

The great advantage of organisation is manifest throughout the report. When explosions have occurred by accident, the places at which they were heard have in many cases been mapped successfully, but accurate records of the time have been rare. With an experimental explosion the observers are ready to note the time to a second at which the sound reaches them. In many of the places from which Prof. Maurain received reports, the agreement between the observers was excellent. Perhaps the best example of precision is provided by the observations at Bordeaux on the first occasion. In the observatory and near by, four observers gave the time as 19 h. 44 m. 5 s., two gave 19 h. 44 m. 4 s., and one 19 h. 44 m. 3 s.

Another advantage is that full information can be obtained as to the meteorological conditions. There were at least two soundings of the upper air in France on each of the three 'La Courtine' days, and the stratosphere was reached on each occasion. Special

[1] Annales de l'Institut de Physique du Globe. Fascicule spécial consacré aux expériences de La Courtine sur la Propagation des ondes aériennes. Paris, 1926.

pilot balloon ascents gave the direction of the air currents in the lowest three or four kilometres.

In the discussion of the observations, Maurain distinguishes between normal and abnormal audibility; for normal audibility the quotient of distance and time is approximately equal to the velocity of sound near the ground, whereas for abnormal audibility the quotient is considerably smaller. In each of the three La Courtine experiments there was a well-defined zone of silence separating zones of normal and abnormal audibility. The maps illustrating the last two experiments are comparatively simple and remarkably consistent. In each, the zone of normal audibility extends about 100 km. N.E. from La Courtine (with the wind), but barely 25 km. in the opposite direction. The zone of abnormal audibility occupies a quadrant to S.W., the minimum distance being about 160 km.

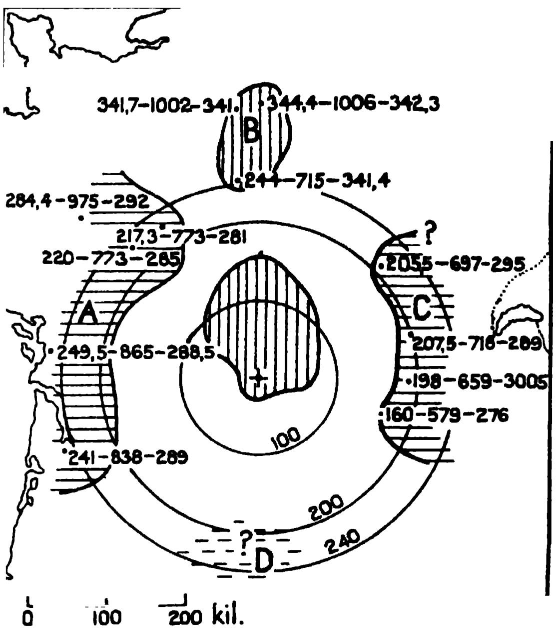


FIG. 1.—The numbers against the dots representing reporting stations are:—The distance from La Courtine in kilometres, the time after the explosion in seconds, and the quotient in metres per second. The circles are not in the original.

Two or three small detached areas of audibility are also shown to the east and north. The map for May 15, which we reproduce (Fig. 1), is of special interest on account of its remarkable symmetry. There were zones of abnormal audibility to east and west of the explosion. A detached region of normal audibility is also mapped in the neighbourhood of Paris, but it is to be noted that the observations in this area were instrumental. The records suggest waves of long period, beyond the range of the ear. With the favouring wind, the long waves travelled better than short ones through the lower atmosphere. As evidence for the favouring wind, it may be mentioned that the Upper Air Supplement of the Daily Weather Report shows that there was a current from the south crossing the English Channel at the cirrus level; the velocity deduced from nephoscope observations was about 100 miles per hour.

In a report of this kind the presentation of the observations in a convenient way is the main issue; it is to be regretted, however, that in the theoretical discussion the author has ignored details and adopted very rough approximations. Although he has been at pains to record the distribution of wind and temperature in the lower atmosphere, he boldly assumes that the sound rays in that region are straight. Moreover, he assumes that the stratosphere is uniform in temperature and composition up to 50 km. above ground, and does not test alternatives. His conclusions are that the high temperature postulated by Lindemann and Dobson for the atmosphere at 60 km. and above (say 300° A.) is not high enough to account for the recurving of the sound rays, and that Von dem Borne's hypothesis of the hydrogen atmosphere must be invoked. He goes so far as to hazard the estimate of 92 per cent. of hydrogen in the constitution of the atmosphere at 116 km., the height suggested for the apex of the path of the sounds heard at Bordeaux.

Fortunately, the observations provide us with a simple criterion by which such statements can be tested. Prof. Wiechert has reminded us recently that there is a close relation between the rate at which the intersection of a sound wave with the earth progresses and the velocity of sound at the apex of the trajectory. In the case of absence of wind and uniform stratification, these are equal. If there is a wind at the level of the apex, the component of the wind velocity in the direction of propagation of the sound must be allowed for. Now, in the La Courtine experiments there are three cases in which the radial velocity of the disturbance in the zone of abnormal audibility can be estimated.

In the first experiment there were well-supported observations to the north-west of La Courtine, at Chinon, and at Angers.

	Distance from La Courtine = X.	Time after explosion = T.	ΔX.	ΔT	ΔX/ΔT
Chinon . .	220 km	773 sec	.	..	.
Angers . .	284 4	975	64 4	202	0 319.

On May 23 there were observations at Angoulême, Rochefort, and Bordeaux, and as the straight line from La Courtine to Angoulême when produced bisects approximately the line from Rochefort to Bordeaux, we may take the average of the co-ordinates of those two stations for comparison.

	X.	T.	ΔX.	ΔT.	ΔX/ΔT.
Angoulême . .	162 km.	614 sec	..	..	..
Bordeaux and Rochefort	244	845	82	231	0 355.

On May 25 there were observations at Vélines between La Courtine and Bordeaux.

	X.	T.	ΔX.	ΔT.	ΔX/ΔT.
Vélines	191 km.	690 sec.	..	..	..
Bordeaux . . .	241	843	50	153	0·327.

It will be seen that in each of these cases the sound travelled across the zone of abnormal audibility with a speed differing but little from the ordinary speed of propagation, which for the temperature 17° C. is about 341 metres per second. In each case the sound was travelling against a light surface wind and would be retarded thereby.

Two deductions may be made:

(1) In the outer part of the zone of abnormal audibility the wave fronts were nearly vertical, the rays nearly horizontal.

(2) Unless the apexes of the sound rays were in a region of strong wind, they must have been at a level where the velocity of sound was about the same as at ground level.

Prof. Maurain's hypotheses are at variance with these deductions from the observations. He contemplates rays, the inclination of which at the ground is only 22° from the vertical, and the velocity of sound at the apex of such sound rays is said to be 786 metres per second. It is clear that further discussion of the observations is called for.

In our diagnosis of the conditions, we start with the known facts with regard to the state of the atmosphere on May 15. As a good approximation we take the temperature of the surface air as 290° A., the lapse rate of temperature $6\frac{2}{3}°$ per km. up to 12 km., and assume a uniform temperature 210° from 12 km. upwards.

The region of uniform temperature may be supposed to extend to a height H_2. Above H_2, temperature is higher. It may be supposed that at the height H_3, temperature is the same as on the ground, 290° A., the inverted lapse rate being the same from H_2 to H_3 and beyond. With these assumptions, wind being ignored, a sound ray consists of arcs of cycloids in the troposphere and the upper atmosphere and of straight lines in the stratosphere.

For a ray starting with a given inclination to the horizon, the range, etc., can be expressed as linear functions of H_2 and H_3. For example, for a ray starting with the inclination $\psi = 15°$, we have the formulæ:

Range in kilometres $= X = 17{\cdot}8 - 5{\cdot}46H_2 + 8{\cdot}35H_3$
Time of passage in seconds $= T = 30{\cdot}54 - 14{\cdot}55H_2 + 26{\cdot}64H_3$.
Height of apex in kilometres $= Z = 1{\cdot}26H_3 - 0{\cdot}26H_2$.

The observations of audibility give values of X and T and, if the inclination of the sound ray is assumed, such formulæ can be used to determine H_2 and H_3.

Four examples are quoted in the following table:

	X.	T.	ψ.	H_2	H_3	Z.	θ	V.
1.	220	773	15	32	45	48·6	311	0·354.
2.	220	773	5	33	44	44·1	292	0·343.
3.	284	975	0	34	51·5	51·5	290	0·341.
4	160	579	20	30	37	40·7	328	0·363.

ψ = initial inclination of ray, θ = temperature at height Z; V = corresponding velocity km./sec.

In the first two, the values of X and T are those appropriate for Chinon on May 15; the alternative values 15° and 5° are assumed for the inclination.

In the third example, the figures for Angers are used, this being a case of a very long range, and in the fourth example, the figures for Unieux are selected to illustrate a very short range.

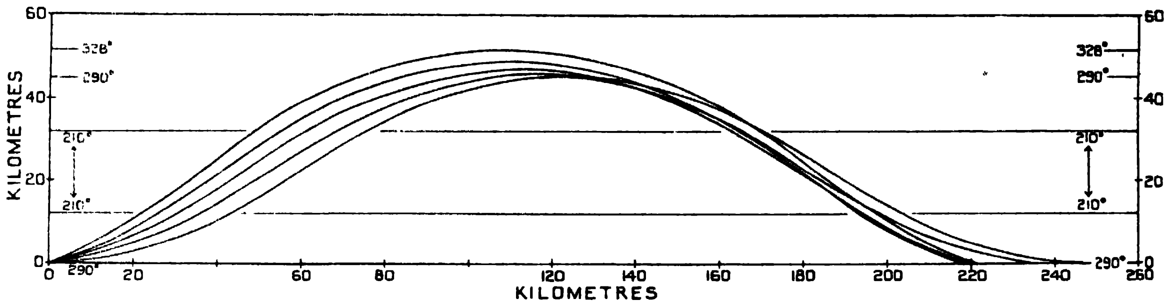
It will be seen that in each of these cases it is indicated that the region of high temperature begins at about 30 km. above ground. The apex of the specified ray is between 40 and 50 km. above ground, and the temperature there is in the neighbourhood of 300° A.

Values of H_2 and H_3 having been determined, we can compute the values of X and T for rays of various inclinations. Thus, if H_2 is 32 and H_3 is 45·2, we obtain the following table:[2]

ψ_0.	X.	T.	ΔX.	ΔT.	$\Delta X/\Delta T$
0	247·5	853·7	..	.	..
5	234·4	815·4	13·1	38·3	0·342.
10	225·3	789·0	9·1	26·4	0·345.
15	220·3	774·8	5·0	14·2	0·352.
20	219·8	773·3	·5	1·5	..
25	224·3	785·6	−4·5	−12·3	0·370.

It will be seen that the range is a minimum for an inclination about 18°. The figures in the last column illustrate Wiechert's principle.

The course of the rays in this example is illustrated in Fig. 2. The figure shows how the rays which return to earth are distributed over a rather narrow zone. That the zone of abnormal audibility is actually wider in observed cases is no doubt to be explained by the complication introduced by wind. The computation of the exact forms of rays with the influences of wind and temperature both taken into account is very cumbersome. To discover a hypothetical distribution of both elements consistent with all the reported observations would therefore require much laborious arithmetic. It is to be hoped that some one will carry this through. It is not likely, however, that the general result, that the observations imply a region of high velocity and high temperature between 30 and 50 km. above ground, will be modified. That this was probably the interpretation of the La Courtine observations was noticed when the preliminary account was published (F. J. W. Whipple, *Meteorological Magazine*, 1925, p. 16). Wiechert has come to the same conclusion as the result of the study of all the available evidence with regard to abnormal audibility (*Met. Zeitschrift*, March 1926, p. 90).



The existence of high temperatures at great heights was deduced by Lindemann and Dobson from the evidence provided by observations of meteors (*Royal Soc. Proc.* A, vol. 102, 1922, pp. 411-437). That this hypothesis would explain the 'abnormal' audibility of explosions was seen at once. There is, however, an apparent discrepancy. Lindemann and Dobson considered that the stratosphere with its uniform temperature might be regarded as reaching nearly to

[2] The figures quoted for 15° elevation do not tally precisely with the formulæ for X and T in which the coefficients have been rounded.

60 km., and credited the higher temperature to the region above that level. The discussion of audibility brings the transition down to 30 km. It seems, however, that the meteor observations are not inconsistent with this modification of the hypothesis.

In Fig. 3A, which is reproduced from part of Fig. 3 of Lindemann and Dobson's paper, the density of the air at different levels is shown by crosses and dots. Each cross shows the density computed for the point of appearance of a meteor, each dot that for a point of disappearance. The curve shows the density calculated on the assumption of a uniform temperature 220° at all levels above 12 km. The curve runs from 220° to 300° occurs between 30 km. and 40 km. The fit is now a little better. Finally, in Fig. 3D, I have made the rise of temperature begin at 30 km. and assumed a regular increase up to 50 km. At that level and beyond, the temperature is 380°. The assumptions are now in reasonable agreement with the observations.

It is difficult to believe that the atmosphere at 60 km. is really at a temperature above the normal boiling-point of water. That seems, however, to be the logical conclusion from the theory of Lindemann and Dobson. For our present purpose the essential point is that the meteor observations do not

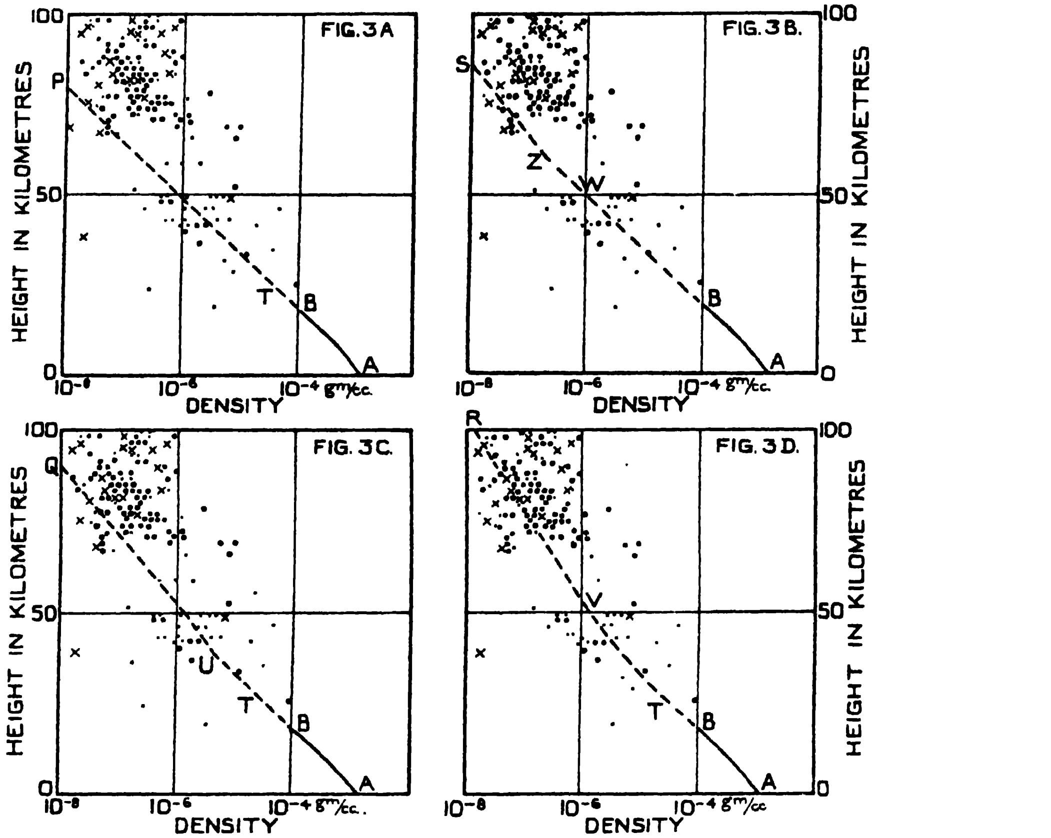


FIG. 3.

fairly through the points representing meteor observations below 60 km. As Lindemann and Dobson point out, above 60 km. the meteor observations "all indicate densities very much greater than those calculated on the assumption of a uniform air temperature of 220° A., but consistent with a considerably higher temperature." They state that the rate of change of density with height shows that the temperature is probably about 300° A., but how this estimate is reached is not clear. I have shown in Fig. 3B the curve which represents the relation between density and height on the assumption that temperature is 220° from 12 km. to 50 km., that there is a uniform gradient to 60 km., and that temperature above 60 km. is 300°. It will be seen that the curve does not represent the meteor observations at all well. In Fig. 3C I have adopted the hypothesis that the transition conflict with the hypothesis suggested by the phenomenon of abnormal audibility, *i.e.* that temperature is about 220° up to 30 km., about 300° at 40 km., and possibly higher above that level.

The apparent inconsistency between the theory of Lindemann and Dobson and their conclusions was pointed out recently by C. M. Sparrow, who interprets their diagram as implying a temperature of 480° (*Astrophysical Journal*, 63, March 1926, pp. 90-110). Sparrow does not accept the theory, and puts forward one of his own, which does not require high temperatures at all. The reply of Lindemann and Dobson to Sparrow's arguments has not yet appeared.

Realisation of the probability that the transition from the uniform temperatures of the stratosphere to much higher temperatures begins at the comparatively modest height of 30 km. makes it desirable to extend

the range of soundings by free balloons to that height, and beyond. By the proper choice of balloons that should be possible.

Another line of attack is also open. We are familiar with the fact that, during the War, gunfire was heard regularly at distances exceeding 100 miles. Why should not similar observations be made systematically in peace time? I should like to inquire whether gun practice at Portland is heard in South Wales. If there is any quiet spot in that region where the sounds are heard frequently, observations should be timed and, with a little organisation, valuable information would be obtained. The advantage of frequent observations of this kind as compared with the occasional 'big bang' is obvious.

Since this article was written I have had an opportunity of testing the possibility of timing the passage of the sound of gunfire. Listening at Grantham on June 28 for the discharge of guns at Shoeburyness, 115 miles away, I found that the time of passage increased gradually from 10¾ to 11½ minutes and then began to decrease. Details have been published in the *Meteorological Magazine* for August.

Obituary.

Dr. J. F. Hall-Edwards.

We regret to record the death on August 15, at the age of sixty-seven years, after many years of suffering due to extensive X-ray injuries, of Dr. J. F. Hall-Edwards. He was educated at King Edward's School and at Queen's College, Birmingham, and after qualifying in medicine he went into practice. Soon after the discovery of X-rays, Dr. Hall-Edwards took up their application in medical work and was one of the earliest authors in radiography. He served in the South African War as surgical expert in X-ray work to the Imperial Yeomanry Hospitals at Deelfontein and Pretoria, receiving the Queen's medal with four clasps. In spite of disabilities which might well have deterred him from any further executive work, he applied for and received a commission as temporary Major in the R.A M.C. at the outbreak of war in 1914, and served in a radiological capacity to such effect that official recognition of his services was made on two occasions. He was an honorary member of the Röntgen Society and the author of several original papers in the journals of this Society and of the Electro-therapeutic Section of the Royal Society of Medicine.

Dr. Hall-Edwards made a great fight for many years against the insidious damage which he had suffered when using X-rays in his medical work. Like other pioneers he suffered because protective methods were unknown. His services in the public cause which so unhappily affected him, were recognised by the award of a Civil List pension in 1908, and later, in 1922, he received the Carnegie Hero Trust Medallion with an annuity.

S. Russ.

We regret to announce the following deaths:—

Dr. Charles W. Eliot, for forty years president, and since 1909, president emeritus of Harvard University, who was largely responsible for raising Harvard to its present high position among the universities of the world, on August 22, aged ninety-two years.

Dr. D. E. Flinn, formerly medical inspector of the Local Government Board, Ireland, editor of the *Health Record* and author of works on public health and hygiene in Ireland on August 18, aged seventy-six years.

News and Views.

Sir Arthur Evans's paper on "The Shaft Graves of Mycenæ and their Contents in Relation to the Beehive Tombs," which was read before the Anthropological Section of the British Association at Oxford, was something in the nature of a bomb-shell, of which the effects will be far-reaching. The relation of the great beehive tombs at Mycenæ, which were found empty of their sepulchral contents, to the shaft-graves, so rich in sepulchral relics, found by Schlieman within an extension of the Acropolis wall, has always been a puzzle to archæologists. Sir Arthur's paper revived a theory, first put forward by Prof. Gardner and arrived at independently by himself, that at a time of danger the royal burials had been transferred from the mausolea outside the walls to a site which could be included within the enceinte. This theory has not found favour among archæologists, and the view generally held is that the two classes of tombs correspond to earlier and later dynasties at Mycenæ. Mr. Wace recently has carried the matter further and suggested that the two finest shaft-graves, the "Treasury of Atreus" and the "Tomb of Clytemnestra," belong to the latest groups, making them contemporary with a time when the Palace of Knossos was in ruins and the civilisation of Crete on the downward path. Sir Arthur Evans's latest discoveries render this theory untenable. He has found decorative sculptures, not later in date than the end of the Third Middle Minoan period and in vogue about 1700 B.C., which run parallel with those of the façade of the "Atreus" tomb. Vases characteristic of the same epoch were found in the "Tomb of Clytemnestra." He was able to demonstrate archæologically that the finest of the beehive tombs belong to the same date as the earliest elements in the shaft graves, and that both are equally Minoan. On this view their culture, with the exception of certain intrusive barbaric elements, can no longer be regarded as a 'mainland' culture and, as Sir Arthur pointed out, the term 'Helladic' as applied to it becomes a misnomer.

Sir Frederick Keeble, Sherardian professor of botany in the University of Oxford, has accepted an

appointment with the Synthetic Ammonia and Nitrate Co., which is associated with Messrs. Brunner, Mond and Co., for the promotion of research in the application of synthetic nitrogen compounds to agricultural purposes. He will probably be released from his chair at Oxford at the end of next term, and start upon his new duties in January. This appointment marks a further step in the movement towards a closer association of fundamental scientific research with commercial enterprises in connexion with agriculture. The growing use of artificial fertilisers renders it imperative that possible fresh sources of supply should be investigated and the value of the products thoroughly tested. As a measure of economy and as a means of protecting agriculturists from loss that might be incurred by using new and comparatively untried fertilisers, research with regard to their economic application is essential, and it is this that Sir Frederick Keeble will endeavour to foster. His wide and varied experience has already brought him into contact with certain aspects of the problem, for on the practical side he has served as controller of horticulture to the Food Production Department of the Board of Agriculture, as assistant secretary to the Board of Agriculture, and as director of the Royal Horticultural Society's Gardens at Wisley, and on the scientific side as professor of botany at Reading and at Oxford. The possibilities in connexion with the use of synthetic nitrogen compounds as fertilisers are of great importance to agriculture, as was pointed out by Sir Daniel Hall in his presidential address at Oxford to Section M (Agriculture) of the British Association, which appears elsewhere in this issue, and the development of this line of work will be followed with much interest.

FURTHER records of the British earthquake of August 15 show that the disturbed area is much larger than was at first supposed, for it was felt at King's Lynn, Gainsborough and Harrogate, so that the total area shaken may amount to 60,000 square miles. This is a high estimate, but it must be remembered that the shock was felt chiefly in upstair rooms and at a time when there were few disturbances to hinder its observation. The position of the epicentre is still uncertain, but it is probably nearer Ludlow than Hereford. That the depth of the focus was considerable is clear from the slow decrease outwards in the strength of the shock in the central district, and from the large area shaken. The shock seems to have been registered at most British stations. The interesting record obtained at Kew is reproduced in the *Daily Express* for August 17. At Stonyhurst, according to the Rev. J. P. Rowland, S.J. (*Times* for August 20), the first preliminary tremors began at 3h. 58m. 46s. A.M. (G.M.T.), and the second at 3h. 59m. 5s., implying that the origin was 103 miles from the observatory or close to Ludlow. "The chief element of uncertainty," he adds, "lies in the determination of the time of commencement of the preliminary tremors, which are very small and difficult to read."

WHAT was probably the first important geological discovery from the air was made in 1920 by Dr. P. Chalmers Mitchell in the course of *The Times* African aeroplane flight. Between Khartum and Wady Halfa the Nile follows an S-shaped course. Flying over the unexplored country within the southern loop of the S, Dr. Mitchell observed a great plain of lava diversified with a number of craters and resembling, as he said, "an enlarged view of the moon." Part of this previously unvisited volcanic field has now been explored by motor car by Mr. H. C. Jackson (*The Times*, August 18). South-west of Sani Wells two conspicuous extinct volcanoes were found; one of the somma type, and the other, graphically called "the Place of Gloom," with an apparently complete crater "of awe-inspiring dimensions." Dr. Mitchell thinks that these craters lie to one side of those over which he passed, and states that Dr. Grabham, the Government geologist of the Sudan, hopes soon to make a survey of the area. Geologists will await with interest the petrological and tectonic description of the field, for its situation is in a line with the western branch of the Rift Valley system, though far to the north of any hitherto suspected continuation of that branch. It is clear from this example alone that many parts of the world may still hold surprises, even for geographical explorers.

THE president of the Board of Trade has appointed a standing committee to consider and advise on questions connected with the economic use of fuels and their conversion into various forms of energy, having regard to national and industrial requirements and in the light of technical developments. The members of the committee are: Sir Alfred Mond, M.P. (chairman), Mr. J. Baker, M.P., Mr. Mark Brand, Sir John Cadman, Sir Arthur Duckham, Sir William Hart, Mr. Frank Hodges, Prof. F. A. Lindemann, Sir David Llewellyn, Mr. M. Mannaberg, Mr. C. H. Merz, Sir Alexander Walker, and Mr. D. Milne Watson. The secretary of the committee is Mr. W. Palmer, and the assistant secretary Mr. R. J. Moffatt. All communications should be addressed to the secretary, National Fuel and Power Committee, Board of Trade, Great George Street, S.W.1.

PROF. ELLIOT SMITH, in the *Morning Post* for August 23, again raises the question of the origin of American culture, apropos of the articles by Dr. T. W. Gann on his discoveries on ancient Maya sites in Central America, which appeared in that journal in the early part of the year. Prof. Elliot Smith now offers the interesting suggestion that the remarkable stone causeways of the Maya found by Dr. Gann are distinctive of work of that period in Indo-China and Java, where there were definite reasons for their construction, and that they were introduced from those countries into Central America, where, however, the reasons for their construction no longer existing, they continued to be constructed from force of habit. He goes on to refer to the arguments recently advanced by Dr. C. Handy that the Maya temple and the Polynesian oracle-house were both copies of the Cambodian temple. A third class of evidence to

which Prof. Elliot Smith directs attention is connected with the cultivation of the sweet potato. The methods of cultivation employed are identical not only in New Zealand by the Maoris and in America, but also throughout Oceania, Cambodia, China, and Japan. Further, it is held that *Kumara*, the Maori word for the sweet potato, also occurs in Ecuador and Peru as *Kumar*, but in addition, F. W. Christian has recently suggested that the word itself is to be derived from the Sanskrit word for the white lotus.

MAJOR FRANCO and Capt. Ruiz de Alda have published a book "de Palos al Plata" giving an interesting record of their adventurous voyage in a seaplane across the South Atlantic from Palos in Spain to Buenos Ayres. They make it clear that an important factor in their success was due to the Marconi direction finder and the radio telegraphic apparatus they carried. On several occasions the direction finder prevented them from making unnecessary detours. There was a fog when approaching Las Palmas. They signalled the radio station there to send continuous signals so as to ensure a good descent. This was immediately done, the signals increasing in loudness until they were directly over Las Palmas, and a good descent was made. They experienced bad visibility again when approaching San Vincente, and again the direction finder proved to be of the greatest value. During their flight they were frequently in communication with passing ships, which sent them their bearings and sometimes sent radio messages announcing their progress to their next stopping place. The authors conclude that the direction finder enabled them to navigate with a maximum inaccuracy of about 3°. This is equivalent to efficient dead reckoning navigation and even to very fair astronomical navigation. They consider that radio telegraphy is indispensable for flights over the sea or sparsely populated countries.

RESULTS of meteorological observations made at the Radcliffe Observatory, Oxford, in the five years 1921–1925, prepared under the direction of Mr. H. Knox-Shaw, Radcliffe Observer, have recently been published by order of the Radcliffe Trustees. The work consists of five annual parts which deal with the observations for the several years. Commencing with 1925, changes in the routine of observation have been introduced; the numbers of eye-readings have been reduced from three to one each day, and the photographic barograph and thermographs which have been in use since 1881 have been superseded. Various other alterations of smaller detail have been introduced, but they are clearly stated. Now that observations have been recorded for seventy-five years or thereabouts, the mean results of barometer, temperature, and rain are as accurate as they will ever be. The mean of the maximum or day temperatures is 70°·8 F. in July, which is the warmest month of the year, and the mean of the day readings in January, the coldest month of the year, is 43°·7 F. The mean of the minimum or night readings for the corresponding months are respectively 53°·3 F. and 34°·5 F. The rainfall for seventy-five years gives the annual average 25·99 in. The wettest month is October, with an average fall of 2·84 in., and the second wettest month is July, with 2·58 in. The driest month is February, with 1·65 in., and the next driest March, with 1·73 in.; but making allowance for the different lengths of the two months, less rain falls on a March day when the average daily fall is 0·056 in., while in February it is 0·058 in. The sunshine records cover forty-five years; the sunniest months are May and June, each with average sunshine for 194·5 hours; the least sunny month is December, with the average sunshine 43·8 hours.

ACCORDING to a despatch of the Cairo correspondent of the *Times*, which appears in the issue of August 16, Mr. Alan Rowe, field director of the Palestine Expedition of the University Museum, Philadelphia, has succeeded in identifying the two temples of the Philistines mentioned in the First Book of Chronicles, x. 10. Of the four temples at Beisan (Beth-shan) built during the Egyptian occupation, two belong to the reign of Rameses II., and of these the southern is identified with the 'Temple of Dagon,' which was dedicated to the warrior god Resheph; the northern, which was dedicated to the warrior goddess Antit-Ashtoreth, was the 'House of Ashtoreth.' It is conjectured that a sanctuary was established in one or other of these temples by David after he had destroyed and partially reconstructed them. A consideration of the results of the season of 1925, and the examination of the archæological objects then obtained, has afforded material for suggestion as to the relation subsisting between Crete, Anatolia, and Philistia before the driving out of the Philistines by King David. The Egyptian mercenary troops who occupied Beth-shan appear to have included an Ægean-Anatolian element before the coming of the Philistines. The walls of the temples of Seti I. and Rameses II. apparently were built by the mercenaries themselves. Some bricks bear signs identical with certain Minoan signs, and not only are the cylindrical cult objects and ring flower-stands Minoan, but also they do not appear on the site before the time of Seti I. The presence of Cretans among the mercenaries had not previously been recognised.

IN the July issue of the *Quarterly Review* Mr. Robert Steele has an illuminating article on the early days of chemistry. He points out that in the Dark Ages of Europe there were two great civilisations, still at the height of their powers, with a foothold in Europe, namely, the Byzantine and the Arab. Byzantium was, however, cut off from Atlantic Europe, whereas the Arab civilisation seems from the first moment of reviving curiosity as to science to have been that to which all eyes turned, in spite of the difference of religion and language. By the middle of the twelfth century a learned world had come into being in Europe, but this renaissance was literary: it knew nothing of science. A century later, however, science

was beginning to come into its own, through the efforts of such translators as Adelard of Bath, Gerard of Cremona, Robert of Chester, and Plato of Tivoli. Among the other Greek sciences which thus came to Latin Christianity by way of the East was alchemy, which had been studied widely and enthusiastically by the Muslims. Mr. Steele's sketch of alchemy in Islam is brief but clear, and by basing it upon recent investigations into this subject he has avoided the errors and misconceptions which are commonly met with. His unrivalled knowledge of medieval Latin alchemy has enabled him to present the salient features of an interesting period in a way which the general reader will find easy to follow and the specialist extremely suggestive.

MR. THOMAS SHEPPARD, director of the Hull Museum, has issued (*Hull Museum Publications*, No. 87) a catalogue of the various exhibits relating to shipping and fisheries which are permanently housed in a special building presented by the late Mr. C. Pickering and situated in Pickering Park, Hull. At one time the whaling trade at Hull was of immense importance, and from it has sprung the present fish and oil trades of that port, which have now grown to an enormous size. It is, therefore, a fitting centre for an exhibit of this kind, and much trouble has been taken to bring together all relics of the old whaling industry which was connected with Hull so early as 1598. The collections are of remarkable interest, embracing as they do an historical series of whaling implements and many valuable old prints and paintings representing the gradual growth of the shipping and fisheries industries. There are many other things in the museum, which is by no means confined to whaling, but all are connected with shipping, fisheries, or exploration in some way, and there is a nucleus of a good library on these subjects. We note that the Adélie penguin (No. 174), brought by the *Terra Nova* from Capt. Scott's last Expedition, is unfortunately described as coming from the Arctic, instead of the Antarctic. Mr. Sheppard is to be congratulated on the catalogue, which adds very much to the value of this interesting little museum.

THE Board of Education has issued a "Report on the Science Museum for the Year 1925." Our copy is marked "For Official Use"; at the same time it is said to be published by H.M. Stationery Office at 1*s*. net. The restriction of the report to 24 pages does not permit elaborate treatment, but enough is said to show that many objects of considerable interest were placed on exhibition during the year. The more important among them were mentioned in NATURE at the time. The value of this museum may be inferred from three classes of visitors. School children come in large numbers, both on their own account and under the guidance of their own teachers. Students make much use of the collections. Officers and technical experts have found here alone the evidence that enabled judgment to be passed on various claims arising out of the War. The space allotted to the exhibition galleries is therefore fully justified. At the close of 1925 it amounted to 155,000 square feet, and the addition of galleries giving 22,000 square feet was authorised by the Government. Even this, however, will not suffice, and of it 45,000 square feet is in old buildings not considered sufficiently fire-proof. "The construction of the centre block, to provide about 100,000 square feet, is therefore an urgent need." The War, while retarding the building operations, gave a great impetus to invention, and thus, on both counts, enhanced the congestion. The Science Museum, it should be remembered, is only one of a number of rapidly expanding institutions in a limited area.

IT is stated in *Science* that the gold medal of the American Geographical Society has been awarded to Dr. Erich von Drygalski, professor of geography in the University of Munich and leader of the German South Polar Expedition of 1900 to 1903.

THE following have been elected officers of the Röntgen Society for the session 1926–1927: *President*, Mr. N. S. Finzi; *Vice-Presidents*, Dr. Robert Knox, Prof. A. W. Porter, Prof. S. Russ; *Hon. Treasurer*, Mr. Geoffrey Pearce; *Hon. Editor*, Dr. G. W. C. Kaye; *Hon. Secretaries*, Mr. Russell J. Reynolds, Prof. F. L. Hopwood.

A QUANTITY of palæolithic implements, stated in the *Times* of August 17 to number more than 200, has been obtained from a gravel pit, at a depth of 12 feet, on the City of Norwich sewage farm at Whitlingham. The discovery is due to Messrs. H. H. Halls and J. E. Sainty, who, in examining the material thrown from the pit by workmen, found two well-made examples of the hand-axe. Mr. J. Reid Moir has examined the deposits and the implements. He has pronounced them to be of Acheulean type, and considers that the gravels in which they were found were laid down just before the third glacial epoch. The implements exhibit a brownish-yellow patination and some exceed 1 ft. in length.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant bacteriologist in the department of pathology and bacteriology of the University of Sheffield—The Registrar (September 11). A lecturer in mathematics at University College, Nottingham—The Registrar (September 14). A junior technical officer in the aerodynamics department of the Royal Aircraft Establishment—The Employment Department, R.A.E., Farnborough, Hants (September 18, quoting Reference A. 122). An engineer to take charge of the Wood Preservation Section of the Forest Products Research Laboratory of the Department of Scientific and Industrial Research—The Secretary of the Department, 16 Old Queen Street, S.W.1 (December 1). A teacher of biology at Gordon College, Khartoum—The Sudan Government London Office, Wellington House, Buckingham Gate, S.W.1. A part-time lecturer in mathematics at Birkbeck College—The Secretary, Birkbeck College, Breams Buildings, Fetter Lane, E.C.4.

Research Items.

MUSIC OF THE SAN BLAS INDIANS.—Advantage was taken of the opportunity afforded by the presence of Tule Indians of Panama in Washington in 1924, to investigate their physical characters and certain aspects of their culture. It will be remembered that the chief point of interest about these Indians, who were brought to the States by Mr. R. O. Marsh, centred in the question whether there was among them a truly 'white' element, as Mr. Marsh claimed. Observations on their music were made by Frances Densmore, and these are now published as No. 11, Vol. 77 of the *Smithsonian Miscellaneous Publications*. The "official musicians," with the chief and the doctors, are the most important people in the villages. Of these the chief may act as a doctor, but not the musician. There are four musicians, two "Chief" and two "Assistant Musicians," in each village who know the songs and teach them for pay. Social gatherings, weddings, etc., are attended by one chief and one assistant musician, never more, for the entertainment of the people. In addition to the songs sung for entertainment there are songs with a definite purpose, such as the treatment of the sick, and songs sung as "charms" which are sold by the doctors. The principal instruments are the flute and the panpipes. The man from whom the songs in the present record were obtained was an amateur who had learnt his songs, some thirty in all, from the official musician. The first song he had learnt was that which brought success in catching a turtle. He also learnt the medicine man's songs, though not himself a medicine man. These include songs to make medicinal herbs effective, to cure headache and other ailments, and the songs that were sung after a man's death. The vocal and instrumental music of the Tule Indians is a form not hitherto recorded. It appears that though the substance of the words and the general character of a song is learnt, each performance is an improvisation. The tone is artificial and extremely difficult to acquire. It is very hard, with a pinched forced quality. The principal occasions for singing were the treatment of the sick, the scene after a burial, the maturity of a young girl and her wedding.

THE AUSTRALIANS AND SOUTH AMERICA.—In No. 18 of the *Compte rendu sommaire de la Société de Biogéographie*, Dr. Paul Rivet discusses the possible routes which might have been followed by the Australians in the migrations postulated to account for the Australian linguistic elements which he claims to have discovered in the language of the Ona of Tierra del Fuego. The sea route across the Pacific is out of the question in view of the scanty equipment of the Australian for navigation. No evidence can be brought forward to support the view that the Australians entered America from the north as did the immigrants from Asia. A third hypothesis was suggested by Mendez-Correa, namely, that they came by the south. The journey might have been performed by making use of the islands of Auckland, Campbell, Macquarie, Esmeralda, Wilkes Land, King Edward VII. Land, and Grahamland as stages. The powers of endurance of cold displayed by the Ona, which surpass those of the Eskimo, might be a result of a prolonged sojourn in these inhospitable regions. In present conditions, however, it is difficult to admit that the islands and shores of the Antarctic are habitable. It is, therefore, desirable to investigate whether there has been a change in climate in this area sufficiently recent for linguistic resemblances to survive, or whether there has been a glacial extension sufficiently marked to shorten the crossing by sea and on which the people could have found game for their subsistence. In discussion it was suggested that the zoological evidence pointed in the direction of this hypothesis and possibly to an extension of Tasmania to the Antarctic, while the geographical and bathymetric distribution of echinoderms suggested a more temperate climate and warmer water at one time in the Antarctic area.

EARLY DEVELOPMENT OF HUMAN EMBRYO.—In the latest volume of "Contributions to Embryology" (Vol. 17, 1926, *Carnegie Institution Publication*, No. 362) Profs. G. W. Bartelmez and H. M. Evans have published a detailed account of the development of the human embryo during the period of somite formation, including embryos with two to sixteen pairs of somites. The material dealt with comprises twenty-five embryos belonging mostly to the collections of the Department of Embryology of the Carnegie Institution and the Department of Anatomy at the University of Chicago. The memoir, which is illustrated by a fine series of plates, deals with many points of interest. It is shown that the cranial flexure is present from the beginning of somite formation, and is due primarily to the more rapid growth of the dorsal as compared with the ventral lamina of the mid-brain folds. The asymmetry, which in the case of the neural folds is a striking feature of the external form, is quite as marked in other systems. It is interpreted as due to localised differences in the rate of growth on each side. Differentiations in the ectoderm foreshadow certain regions of the head, and definite parts of these contribute to the formation of certain of the cranial ganglia in the 16-somite stage. The closure of the neural folds begins at the level of the fourth pair of somites in the 6- to 7-somite stage, and the neural crest is proliferated at about the same time. The origin and early development of many other structures are described in detail, and their phylogenetic and physiological significance are pointed out. Owing to the comparatively large amount of material available, the time-sequence in which the various parts appear has been traced far more fully than in any previous accounts of early human development.

NEUROGLIA CELLS.—Those who are interested in the study of neuroglia will welcome the paper by Dr. C. Da Fano in the current (June) issue of the *Journal of the Royal Microscopical Society*, in which the recent methods for demonstrating the neuroglia cells are carefully described. These methods were devised by Cajal and Del Río-Hortega, but Dr. Da Fano has given due weight in his account to his personal experience gained chiefly through a short stay in Del Río-Hortega's laboratory in Madrid. It is impossible to give a summary of the methods; the paper, which is illustrated by eight figures, should be consulted for the details of the several processes.

SOUTH AFRICAN MOLLUSCA.—Two papers on mollusca from South Africa appear in the *Annals of the Natal Museum*, vol. 5. Mr. J. R. le B. Tomlin contributes a paper on marine forms, including the description of eleven supposed new species, and one new genus belonging to the Tectibranchiata. This last, *Alexandria natalensis*, n. gen. et sp., the author places in the Acteonidæ on account of the shell apex, the radula and operculum. The paper is illustrated by one of Miss G. M. Woodward's excellent plates. H. C. Burnup supplies Part 2 of his memoir
